

THE PHYSICAL REVIEW

A JOURNAL OF EXPERIMENTAL AND
THEORETICAL PHYSICS

CONDUCTED BY
THE
AMERICAN PHYSICAL SOCIETY

BOARD OF EDITORS

Managing Editor JOHN T. TATE, University of Minnesota, Minneapolis
I. S. BOWEN, R. S. MULLIKEN, H. D. SMYTH, E. U. CONDON, C. J. DAVISSON,
F. K. RICHTMYER, K. F. HERZFELD, A. W. HULL, F. W. LOOMIS

VOLUME 36, SECOND SERIES
JULY-DECEMBER, 1930

THE PHYSICAL REVIEW
MINNEAPOLIS, MINN.

CONTENTS

JULY 1, 1930

A Note on the Spectra of Doubly and Trebly Ionized Lead	STANLEY SMITH	1
Spark Spectrum of Cobalt (Co II)	J. H. FINDLAY	5
Spectra of Gases Lighted with Strong Electrical Discharges	E. O. HULBURT	13
Computation of the Effective Cross Section for the Recombination of Electrons with Hydrogen Ions	E. C. G. STUECKELBERG AND PHILIP M. MORSE	16
Recombination of Ions in Argon, Nitrogen and Hydrogen	OVERTON LUHR	24
Mobilities of Ions in Dry and Moist Air	JOHN ZELENY	35
Excitation Processes in the Hollow Cathode Discharge	RALPH A. SAWYER	44
Analytic Atomic Wave Functions	CLARENCE ZENER	51
Atomic Shielding Constants	J. C. SLATER	57
A Search for the Source of Dielectric Polarization	RALPH D. BENNETT	65
Infrared Filters of Controllable Transmission	A. H. PFUND	71
Velocity of Ultrasonic Waves in Water Vapor	GEORGE E. THOMPSON	77
Unreliability of Photographic Emulsions on Glass for Recording Distances and a Method of Minimizing this Defect	D. COOKSEY AND C. D. COOKSEY	80
Precision Measurements of the Glancing-Angle of Reflection from Calcite for Silver ($K\alpha_1$) X-Rays by the "Method of Displacement"	C. D. COOKSEY AND D. COOKSEY	85
Spherically Symmetrical Field in the Unified Theory	N. ROSEN AND M. S. VALLARTA	110
Gibbs-Dalton Law of Partial Pressures	LOUIS J. GILLESPIE	121
A Rational Basis for the Thermodynamic Treatment of Real Gases and Mixtures of Real Gases	JAMES A. BEATTIE	132
Letters to the Editor		146
Breadth of Compton Modified Line, <i>J. W. M. DuMond</i> —146; Raman Effect in Trimethylethylene, <i>Dorothy Franklin and E. R. Laird</i> —147; Photoionization of Salt Vapors, <i>A. Terenin</i> —147; Raman Effect in Solutions of Sodium Nitrate of Varying Concentration, <i>Vera Sterling and E. R. Laird</i> —148; Calculation of Energy Values, <i>Carl Eckart</i> —149; Some Peculiarities of the Spectrum of the Tungsten Mercury Arc, <i>W. E. Forsythe and M. A. Easley</i> —150; Experimental Evidence for the Existence of Quadrupole Radiation, <i>Rudolf Frerichs and J. S. Campbell</i> —151; Mobility of Na^+ Ions in H_2 , <i>Leonard B. Loeb</i> —152; Interaction between Excited and Unexcited Hydrogen Atoms at large Distances, <i>E. C. Kemble and F. F. Rieke</i> —153.		
Book Reviews		155

JULY 15, 1930

Incomplete Paschen-Back Effect	J. B. GREEN	157
Fine Structure of the K-Radiation of the Lighter Elements	LAWRENCE Y. FAUST	161
Spark Spectra of Silver and Palladium (Ag II and Pd II)—An Extension	H. A. BLAIR	173
Resonance (B-A) Band System of the Hydrogen Molecule	HUGH H. HYMAN	187
Luminescence of Zinc Sulphide Under the Action of Alpha, Beta and Gamma Rays	GEORGE S. GESSNER	207
A Second Ionization Potential in Potassium Vapor	A. L. HUGHES AND C. M. VAN ATTA	214
Absorption and Collision Broadening of the Mercury Resonance Line	M. W. ZEMANSKY	219
Effect of Small Angle Scattering on the Electron Absorption Coefficient	METTA CLARE GREEN	239
Rate at Which Ions Lose Energy in Elastic Collisions	AUSTIN M. CRAVATH	248
Method of Enhancing the Sensitiveness of Alkali Metal Photoelectric Cells	A. R. OLPIN	251
Infrared Absorption of Some Organic Liquids Under High Resolution. Part II	R. BOWLING BARNES	296
Effect of High Pressure on the Near Infrared Absorption Spectrum of Certain Liquids	J. R. COLLINS	305
Adsorption of Methyl Alcohol Films on Rock Salt	SHIRLEIGH SILVERMAN	311
Principal Magnetic Susceptibilities of Bismuth Single Crystals	ALFRED B. FOCKE	319
Discontinuous Changes in Length Accompanying the Barkhausen Effect in Nickel	C. W. HEAPS AND A. B. BRYAN	326
Isotopes of Nitrogen, Mass 15, and Oxygen, Mass 18 and 17 and their Abundances	S. MEIRING NAUDÉ	333
Margules Method of Measuring Viscosities Modified to Give Absolute Values	HOWARD R. LILLIE	347
An Erratum		363

Letters to the Editor	364
Interpretation of the Visible Halogen Bands, <i>Robert S. Mulliken</i> —364; Double Crystal Analysis of Scattered X-rays, <i>Newell S. Gingrich</i> —364; A Remark on the Paper of R. C. Tolman: "Mechanical Treatment of the Temperature Distribution in the Case of Radiation," <i>Wilhelm Anderson</i> —365; A Remark on the Foregoing Letter of W. Anderson— <i>R. C. Tolman</i> —365; Raman Spectra of Geometric Isomers, <i>C. F. Ffolliott</i> —367; Method Offered as a Means of Computing Planck's Constant Without Involving the Charge on the Electron, <i>Allen Lucy</i> —367; Gas Discharge Wave-length List in Extreme Ultraviolet, <i>Janet M. MacInnes and Joseph C. Boyce</i> —368.	
Book Reviews	369

PROCEEDINGS OF THE AMERICAN PHYSICAL SOCIETY

Ithaca Meeting, June 19-21, 1930; Minutes and Abstracts 1-33; Author Index	372
--	-----

AUGUST 1, 1930

Fine Structure of He as a Test of the Spin Interactions of Two Electrons	G. BREIT	383
Singlet System of Oxygen Arc Spectrum and the Origin of the Green Auroral Line	RUDOLF FRERICHs	398
Band Spectra Intensities for Symmetrical Diatomic Molecules	ELMER HUTCHISSON	410
Vibrational Quantum Analysis of the Potassium Infrared Absorption Bands	W. O. CRANE AND ANDREW CHRISTY	421
Rotational Motion of Molecules in Crystals	LINUS PAULING	430
Deflection of Electrons by a Magnetic Field on the Wave Mechanics	LEIGH PAGE	444
Absorption of X-Rays by Lithium	K. C. MAZUMDER	457
Wave-Length Measurements of Gamma-Rays from Radium and its Products	LUVILLE T. STEADMAN	460
Ionization of Carbon Dioxide by Electron Impact	H. D. SMYTH AND E. C. G. STUECKELBERG	472
Ionization of Nitrous Oxide and Nitrogen Dioxide by Electron Impact	E. C. G. STUECKELBERG AND H. D. SMYTH	478
Effect of Intense Electric Fields on the Photoelectric Properties of Metals	ERNEST O. LAWRENCE AND LEON B. LINFORD	482
Magnetic Isotropy of Copper Crystals	CAROL G. MONTGOMERY	498
Tension Coefficient of Resistance of Metals	HARRY ROLNICK	506
Vibrations of a Non-Planar Membrane	GEORGE R. STIBITZ	513
Capillary Retention of Liquids in Assemblages of Homogeneous Spheres	W. O. SMITH, PAUL D. FOOTE AND P. F. BUSANG	524
A Representation of the Dynamic Properties of Molecules by Mechanical Models	C. F. KETTERING, L. W. SHUTTS AND D. H. ANDREWS	531
Relation Between the Raman Spectra and the Structure of Organic Molecules	DONALD H. ANDREWS	544
Elastic Character of the Homopolar Chemical Bond	ROBERT C. YATES	555
Study of the Small Vibrations of Six Particles in a System Analogous to the Benzene Ring	ROBERT C. YATES	563
Coupled Vibrations with Applications to the Specific Heat and Infrared Spectra of Crystals	ARTHUR B. LEWIS	568
Studies in Contact Rectification. II. The Cupric Sulfide-Magnesium Junction	MILTON BERGSTEIN, J. F. RINKE AND C. M. GUTHEIL	587
Letters to the Editor		600
The Presence of Neutral Oxygen in the Gaseous Nebulae, <i>I. S. Bowen</i> —600; Photoelectric Outgassing, <i>Ralph P. Winch</i> —601; Effect of the Earth's Electric and Magnetic Fields on Ions in the Atmosphere, <i>Leigh Page</i> —601; Note on Wave-lengths in the Vacuum Copper Arc, <i>A. G. Shenstone</i> —602; The Electrolytic Dissociation of Nitric Acid as Revealed by its Infrared Absorption Spectrum, <i>E. L. Kinsey and J. W. Ellis</i> —603; The Optical Excitation Function of Helium, <i>Walter C. Michels</i> —604; Metastable Atoms and Electrons Produced by Resonance Radiation in Neon, <i>Irving Langmuir and Clifton G. Found</i> —604; On the Magnetic Deflection of Cosmic Rays, <i>Bruno Rossi</i> —606.		
Book Reviews		607

AUGUST 15, 1930

Report on Notation for Spectra of Diatomic Molecules	ROBERT S. MULLIKEN	611
Application of the Fermi-Thomas Statistical Model to the Calculation of Potential Distribution in Positive Ions	EDWARD B. BAKER	630
Fine Structure in the X-Ray Absorption Spectra of the K Series of the Elements Calcium to Gallium	BEN KIEVIT AND GEORGE A. LINDSAY	648
False Lines in X-Ray Grating Spectra	J. M. CORK	665
Arc Spectrum of Palladium	A. G. SHENSTONE	669
Intensity Measurements in the Spectrum of Nickel and Cobalt	L. S. ORNSTEIN AND T. BOUMA	679

Effect of the Motion of the Nucleus on the Spectra of Li I and Li II - - - - -	D. S. HUGHES AND CARL ECKART	694
Electronic States in the Visible Halogen Bands - - - - -	ROBERT S. MULLIKEN	699
Interpretation of Pressure and High Velocity Vapor Jets at Cathodes of Vacuum Arcs - - - - -	KARL T. COMPTON	706
Secondary Emission from Metals by Impact of Metastable Atoms and Positive Ions - - - - -	W. UYTERHOEVEN AND M. C. HARRINGTON	709
Extinction of Short A.C. Arcs between Brass Electrodes - T. E. BROWNE, JR. AND F. C. TODD		726
Restriking of Short A.C. Arcs - - - - -	F. C. TODD AND T. E. BROWNE, JR.	732
Photoelectric Behavior of Solid and Liquid Mercury - - - - -	DUANE ROLLER	738
Thermodynamic Treatment of Chemical Equilibria in Systems Composed of Real Gases. I. An Approximate Equation for the Mass Action Function Applied to the Existing Data on the Haber Equilibrium - - - - -	LOUIS J. GILLISPIE AND JAMES A. BEATTIE	743
Dielectric Constant of Carbon Dioxide as a Function of Temperature and Density - - - - -	FREDERICK G. KEYES AND JOHN G. KIRKWOOD	754
Some Applications of the Theory of Plastic Deformations of Ductile Metals - - - - -	A. NADAI	762
Attempt to Detect Collisions of Photons - - - - -	A. L. HUGHES AND G. E. M. JAUNCEY	773
Letters to the Editor - - - - -		778
Band Intensities, <i>Joseph Kaplan</i> —778; X-Ray Scattering Coefficient as a Function of Wave-length and Atomic Number, <i>Errol N. Coade</i> —778; Fluorescent Dry Plates for Photographic Photometry, <i>George R. Harrison and Philip A. Leighton</i> —779.		
Book Reviews - - - - -		781

PROCEEDINGS OF THE AMERICAN PHYSICAL SOCIETY

Eugene Meeting, June 19–21, 1930; Minutes and Abstracts 1–25; Author Index - - - - -	783
--	-----

SEPTEMBER 1, 1930

Double Crystal Study of Scattered X-Rays - - - - -	J. A. BEARDEN	791
Energy of $K\alpha_1$ of Copper as a Function of Applied Voltage with the Double Crystal Spectrometer - - - - -	JESSE W. M. DUMOND ARCHER HOYT	799
Projective Relativity - - - - -	OSWALD VEBLEN AND BANESH HOFFMAN	810
On the Theory of the Brownian Motion - - - - -	G. E. UHLENBECK AND L. S. ORNSTEIN	823
Appearance of Forbidden Lines in Spectra - - - - -	L. D. HUFF AND W. V. HOUSTON	842
Hyperfine Structures of Some Cd Lines and the Hypothesis of Nuclear Spin- C. L. ALBRIGHT		847
New Lines in the Arc and Spark Spectrum of He - - - - -	P. GERALD KRUGER	855
Structure of Emission Lines- - - - -	FRANK HOYT	860
Note on Frequency Shifts in Dispersing Media - - - - -	G. BREIT AND E. O. SALANT	871
Theory and Calculation of Screening Constants - - - - -	CARL ECKART	878
Reflection of Cd and Zn Atoms from NaCl Crystals - - - - -	HAROLD A. ZAHL	893
Determination of e/m for an Electron by Direct Measurement of the Velocity of Cathode Rays - - - - -	CHARLOTTE T. PERRY AND E. L. CHAFFEE	904
New Experimental Determination of Effective Cross-Sections for the Quenching of Hg Resonance Radiation - - - - -	M. W. ZEMANSKY	919
Some Measurements of the Longitudinal Elastic Frequencies of Cylinders Using a Magnetostriction Oscillator - - - - -	DAVID S. MUZZEY, JR.	935
Electrical Resistance of Ni and Permalloy Wires as Affected by Longitudinal Magnetization and Tension - - - - -	L. W. MCKEEHAN	948
On the Magnetic Properties of Metals - - - - -	FRANCIS BITTER	978
Scattering of Fast Electrons by Metals. I. The Sensitivity of the Geiger Point Discharge Counter - - - - -	CARL T. CHASE	984
High Potential X-Ray Tube - - - - -	C. C. LAURITSEN AND B. CASSEN	988
Linear Correction for Cathode Ray Oscillograph - - - - -	FREDERICK BEDELL AND JACKSON KUHN	993
Propagation of Luminosity in Discharge Tubes - - - - -	J. W. BEAMS	997
Simple Accurate Method for Measuring the Diamagnetic Susceptibility of Dissolved Substances - - - - -	SIMON FREED AND CHARLES KASPER	1002
Ultrasonic Velocity and Absorption in Oxygen- - - - -	W. H. PIELEMEIER	1005
Thermodynamic Treatment of Chemical Equilibria in Systems Composed of Real Gases. II. A Relation for the Heat of Reaction Applied to the Ammonia Synthesis Reaction. The Energy and Entropy Constants for Ammonia- - - - -	LOUIS J. GILLESPIE AND JAMES A. BEATTIE	1008
Letters to the Editor - - - - -		1014
Wave Mechanics of Deflected Electrons, <i>Carl Eckart</i> —1014; Magnetostriction in Nickel, <i>L. W. McKeehan</i> —1014; Wind Mixing and Diffusion in the Upper Atmosphere, <i>S. Chapman</i> —1014; Evidence for the Richtmyer Double Jump Hypothesis of X-Ray Satellites, <i>Jesse W. M. DuMond</i> —1015; Hyperfine Structure of X-Ray Lines, <i>F. K. Richtmyer, S. W. Barnes and K. V. Manning</i> —1017; The Angular Momentum of the Li ⁺ Nucleus, <i>L. P. Granath</i> —1018; Evidence for Be Isotope of Mass 8 in the BeH Band Spectrum, <i>William W. Watson</i> —1019; The Penetration of Radiation, <i>Elliot Q. Adams</i> —1020; New Bands in the Absorption Spectrum of Mercury, <i>J. G. Winans</i> —1021.		
Errata - - - - -		1022

SEPTEMBER 15, 1930

Canal Ray and Electron Excitation of the Band Spectrum of Nitrogen - - - - -	H. D. SMYTH AND E. G. F. ARNOTT	1023
Angle and Energy Distribution of Electrons Scattered by Helium, Argon and Hydrogen - - - - -	J. HOWARD McMILLEN	1034
Intensity of X-Ray Satellites - - - - -	F. K. RICHTMYER AND L. S. TAYLOR	1044
Analysis of Scattered X-Rays With the Double Crystal Spectrometer - NEWELL S. GINGRICH		1050
Scattering of Fast Electrons by Metals. II. Polarization by Double Scattering at Right Angles - - - - -	CARL T. CHASE	1060
Experimental Determination of the Change in Temperature Accompanying Change in Magnetization of Iron - - - - -	WALTER B. ELLWOOD	1066
New Method of Measuring the Variation of Specific Heats (c_p) of Gases with Pressure - - - - -	E. J. WORKMAN	1083
Note on the Pressure Variation of Specific Heats of Gases Derived from Compressibility Data - - - - -	L. G. HOXTON	1091
Letters to the Editor - - - - -		1096
Relative Efficiency of the Hg-arc Lines in exciting the Raman Spectrum of Benzol, <i>Sister Magna Werth</i> —1096; Orbital Valency, <i>James H. Bartlett, Jr.</i> —1096; Probable Number of Isotopes of Eight Metals as determined by a New Method, <i>Fred Allison and Edgar J. Murphy</i> —1097; Formation of Striae in a Kundt's Tube, <i>Rolla V. Cook</i> —1098; Intensity Changes of Cameron Bands in the Electrodeless Discharge, <i>Harold P. Knauss and Jack C. Cotton</i> —1099; On the Direction of Emission of Photoelectrons from Potassium Vapor by Ultraviolet Light, <i>Ernest O. Lawrence and Milton A. Chaffee</i> —1099; Electrostatic Surface Fields near Thoriated Tungsten Filaments by a Photoelectric Method, <i>Leon B. Linford</i> —1100.		

OCTOBER 1, 1930

Use of the Refraction of X-Rays for the Determination of the Specific charge of the Electron - - - - -	H. E. STAUSS	1101
X-Ray Scattering Coefficient as a Function of Wave-Length and Atomic Number - - - - -	ERROL N. COADE	1109
Atomic Scattering Powers of Nickel, Copper and Iron for Various Wave-Lengths - - - - -	RALPH W. G. WYCKOFF	1116
Theory of Complex Spectra - - - - -	E. U. CONDON	1121
Zeeman Effect in the ZnH and CdH Bands - - - - -	WILLIAM W. WATSON	1134
Principle of Identity and the Exclusion of Quantum States - - - - -	GILBERT N. LEWIS	1144
On the Wentzel-Brillouin-Kramers Approximate Solution of the Wave Equation - - - - -	L. A. YOUNG AND G. E. UHLENBECK	1154
On the Origin of the Bands in the Spectrum of Mercury Vapor - - - - -	S. MROZOWSKI	1168
Abnormal Shot Effect of Ions of Tungstous and Tungstic Oxide - - - - -	JOHN S. DONAL, JR.	1172
Distinction between Contact-Potential Effects and True Reflection Coefficients for Low-Velocity Electrons - - - - -	H. E. FARNSWORTH AND V. H. GOERKE	1190
Current, Pressure, and Frequency Relationships for the Initiation and Maintenance of the Electrodeless Glow Discharge - - - - -	MILTON L. BRAUN	1195
Absorption of Slow Hydrogen Positive Rays in Hydrogen - - - - -	ROBERT E. HOLZER	1204
Velocity Distribution of Secondary Electrons from Molybdenum - - - - -	THEODORE SOLLER	1212
Heat of Formation of Molecular Oxygen - - - - -	L. COVELL COPELAND	1221
Dielectric Constant of Helium - - - - -	J. V. ATANASOFF	1232
Potential and Potential Energy of Space Lattices - - - - -	C. N. WALL	1243
Origin of the Variations in the Sun's Rotational Velocity - - - - -	ROSS GUNN	1251
Triboluminescence - - - - -	R. E. NYSWANDER AND BYRON E. COHN	1257
Letters to the Editor - - - - -		1261
High Voltage Tubes, <i>M. A. Tuve, L. R. Hafstad and O. Dahl</i> —1261; Use of the Pierce Acoustic Interferometer for the Determination of Absorption in Gases for High Frequency Sound Waves, <i>Elias Klein and W. D. Hersberger</i> —1262; The Magnetic Moment of the Li Nucleus, <i>G. Breit and F. W. Doermann</i> —1262; Wind Mixing and Diffusion in the Upper Atmosphere, <i>E. O. Hulburt</i> —1264.		
Book Reviews - - - - -		1265

OCTOBER 15, 1930

Position and Structure of the Modified Line of the Spectrum of Scattered X-Rays - - - - -	F. L. NUTTING	1267
An Experimental Study of the Relative Intensities of X-Ray Lines in the Tantalum L-Spectrum - - - - -	VICTOR HICKS	1273
A Study of the Velocities of H^+ Ions Formed in Hydrogen by Dissociation Following Electron Impact - - - - -	W. WALLACE LOZIER	1285
Ionization of Helium, Neon, and Argon by Electron Impact - - - - -	PHILIP T. SMITH	1293

Ionization Potentials and Probabilities for the Formation of Multiply Charged Ions in Helium, Neon and Argon - - - - -	WALKER BLEAKNEY	1303
Thermionic Emission of Oxide Coated Cathodes Containing a Ni-Ba Alloy Core - - - - -	N. C. BEESE	1309
Shot Effect of the Emission from Oxide Cathodes - - - - -	H. N. KOZANOWSKI AND N. H. WILLIAMS	1314
A Photographic Method of Determining Atomic Structure Factors - - - - -	DAROL K. FROMAN	1330
A Note on the Extrapolation of Atomic Structure Factor Curves - - - - -	DAROL K. FROMAN	1339
Range of the α Particles from Thorium - - - - -	G. H. HENDERSON AND J. L. NICKERSON	1344
Possibilities of the Oscillating Arc in Spectrochemical Analysis - - - - -	E. Z. STOWELL AND W. S. HUXFORD	1348
Electro-Optical Modification of Light Waves - - - - -	L. H. STAUFFER	1352
Optical Excitation Function of Helium - - - - -	WALTER C. MICHELIS	1362
Organic Reactions in Gaseous Electrical Discharge I. Normal Paraffin Hydrocarbons - - - - -	ERNEST G. LINDER	1375
Polarized Fluorescence of Solutions of Rhodamine-B and Uranine - - - - -	ERNEST MERRITT AND DONALD R. MOREY	1386
Mobility of Aged Ions in Air - - - - -	OVERTON LUHR AND NORRIS E. BRADBURY	1394
On the Entropy of Hydrogen - - - - -	D. MAC GILLAVRY	1398
A New Relativity Theory of the Unified Physical Field - - - - -	WILLIAM BAND	1405
Letters to the Editor - - - - -		1413
Effect of Electric Field upon X-Ray Diffraction Pattern of a Liquid, G. W. Stewart—1413; Interpretation of the Spectra of CaF and SrF, A. Harvey and F. A. Jenkins—1413; Structure of K-radiation from C, B, and Be, Martin Soderman—1414; High Efficiencies of Emission from Oxide-Coated Filaments, B. J. Thompson—1415; Negative Ions in Hydrogen and Water Vapor, W. W. Lozier—1417; Wave Mechanics of Deflected Electrons, Leigh Page—1418.		
Book Reviews - - - - -		1419

NOVEMBER 1, 1930

Improved Technique for the Raman Effect - - - - -	R. W. WOOD	1421
Raman Spectra of Benzene and Diphenyl - - - - -	R. W. WOOD	1431
Heats of Condensation of Electrons on Several Metals in Several Ionized Gases - - - - -	C. C. VAN VOORHIS AND K. T. COMPTON	1435
Correlation of Atomic J Values and Molecular Quantum Numbers, with Applications to Halogen, Alkaline Earth Hydride, and Alkali Molecules - - - - -	ROBERT S. MULLIKEN	1440
A New Band in the Absorption Spectrum of Methane Gas - - - - -	DAVID M. DENNISON AND S. B. INGRAM	1451
Transverse Zeeman Effect of the Green Auroral Line; an Experimental Proof of the Existence of Quadrupole Radiation - - - - -	RUDOLF FRERICHS AND J. S. CAMPBELL	1460
Spectral Distribution of Energy Radiated from a New Type of Tungsten Mercury Arc - - - - -	B. T. BARNES	1468
General Electric Type S-1 Lamp as a Spectroscopic Source - - - - -	DONALD DOOLEY	1476
Behavior of a Mercury Vapor Arc with a Jet of Liquid Mercury as Cathode - - - - -	AUSTIN M. CRAVATH	1480
Diffraction of a Circularly Symmetrical Electromagnetic Wave by a Co-axial Circular Disc of Infinite Conductivity - - - - -	JOHN BARDEEN	1482
A Low Grid-Current Vacuum Tube - - - - -	G. F. METCALF AND B. J. THOMPSON	1489
Cataphoresis in Rotating Electric Fields - - - - -	E. M. PUGH AND C. A. SWARTZ	1495
Hall Effect and the Magnetic Properties of Some Ferromagnetic Materials - - - - -	EMERSON M. PUGH	1503
Letters to the Editor - - - - -		1512
The Molecular Field and Atomic Order in Ferromagnetic Crystals and in Hydrogenized Iron, L. W. McKeehan—1512; The Wave Mechanics of Deflected Electrons, Carl Eckart—1514; The Non-Statistical Solution of Einstein's Law of Gravitation in a Spatially Symmetrical Field, Hsin P. Soh—1515.		
Book Reviews - - - - -		1516

NOVEMBER 15, 1930

Scattering of Hard γ -Rays - - - - -	C. Y. CHAO	1519
Fine Structure of Certain X-Ray Emission Lines - - - - -	JOSEPH VALASEK	1523
Correction and Extension of the Series of the Silver Arc Spectrum, Ag I - - - - -	H. A. BLAIR	1531
I. Effect of Gases on the Optically Excited Cadmium I Spectrum - - - - -	PAUL BENDER	1535
II. Optical Excitation of Cadmium Hydride and Zinc Hydride Bands - - - - -	PAUL BENDER	1543
Isotope Effect on Band Spectrum Intensities - - - - -	J. L. DUNHAM	1553
Ultraviolet Light Theory of Aurorae and Magnetic Storms. (Continued) - - - - -	E. O. HULBURT	1560
Dielectric Constant of Ammonia as a Function of Temperature and Density - - - - -	FREDERICK G. KEYES AND JOHN G. KIRKWOOD	1570

Note on the Production of Extremely High Voltages - - - - -	M. A. TUVE	1576
A Two Dimensional Boundary Value Problem for the Transmission of Alternating Currents Through a Semi-Infinite Heterogeneous Conducting Medium - - - - -	HERBERT P. EVANS	1579
Letters to the Editor - - - - -		1589
Polarization of Mercury Lines in Stepwise Radiation, <i>Allan C. G. Mitchell</i> —1589; On the Attempt to Detect Collisions of Photons, <i>S. Vavilov</i> —1590; A Note on Zeeman Patterns, <i>Henry Norris Russell</i> —1590; Raman Effect of HBr and HI, <i>E. O. Salant and A. Sandow</i> —1591; Absorption and Collision Broadening of Resonance Radiation, <i>M. W. Zemansky</i> —1591; On the Incomplete Polarization of the Mercury Resonance Radiation, <i>S. Mrozowski</i> —1591; On the Entropy of Hydrogen, <i>W. F. Giaque and H. L. Johnston</i> —1592.		
Book Reviews- - - - -		1594

DECEMBER 1, 1930

On the Question of the Constancy of the Cosmic Radiation and the Relation of these Rays to Meteorology - - - - -	ROBERT A. MILLIKAN	1595
On the Electrical Resistance of Contacts between Solid Conductors - - - - -	J. FRENKEL	1604
X-Ray Absorption in Gases - - - - -	W. W. COLVERT	1619
Diffraction of X-Rays in Liquids: Effect of Temperature - - - - -	E. W. SKINNER	1625
On the Fluorescence of Quartz Under the Influence of Cathode Rays of Low Voltage - - - - -	HEINRICH PETERS	1631
Pressure and High Velocity Vapour Jets at Cathodes of a Mercury Vacuum Arc - - - - -	E. KOBEL	1636
Photoelectric Emission from Thin Films of Caesium - - - - -	L. R. KOLLER	1639
Magnetic Susceptibility of Gases II. Temperature Dependence - - - - -	FRANCIS BITTER	1648
Magnetic Properties of Certain Pt-Co and Pd-Co Alloys - - - - -	F. WOODBRIDGE CONSTANT	1654
Magnetic Isotropy of a Paramagnetic Alum - - - - -	C. G. MONTGOMERY	1661
A Method for Growing Large Crystals of the Alkali Halides - - - - -	JOHN STRONG	1663
Letters to the Editor - - - - -		1667
Use of the Pierce Acoustic Interferometer, <i>W. H. Pielemeier</i> —1667; Wave Mechanics of Deflected Electrons, <i>E. H. Kennard</i> —1667; Simple Isotopic Constitution of Caesium, <i>K. T. Bainbridge</i> —1668; Problems in Acoustic Interferometry with Gases, <i>J. C. Hubbard</i> —1668; Magnetostriction and Magnetic Hysteresis, <i>L. W. McKeehan</i> —1670; Note on the Source of Dielectric Polarization, <i>Ralph D. Bennett</i> —1670; A Diophantine Equation Connected with the Hydrogen Spectrum, <i>T. H. Gronwall</i> —1671.		
Book Reviews- - - - -		1673

DECEMBER 15, 1930

Polarization of the Continuous X-Rays from Single Electron Impacts - - - - -	BALEBAIL DASANNACHARYA	1675
Spectrum of the Radiation from a High Potential X-Ray Tube - - - - -	C. C. LAURITSEN	1680
Multiple Scattering in the Compton Effect - - - - -	JESSE W. M. DUMOND	1685
Design and Technique of Operation of a Double Crystal Spectrometer - - - - -	JESSE W. M. DUMOND AND ARCHER HOYT	1702
Value of e/m by Deflection Experiments - - - - -	G. E. UHLENBECK AND L. A. YOUNG	1721
Relativistic Wave Mechanics of Electrons Deflected by a Magnetic Field - - - - -	MILTON S. PLESSET	1728
Hyperfine Structure of S and P Terms of Two Electron Atoms with Special Reference to Li^+ - - - - -	G. BREIT AND F. W. DOERMANN	1732
Thermoanalysis of Metal Single Crystals and a New Thermoelectric Effect of Bismuth Crystals Grown in Magnetic Fields - - - - -	ALEXANDER GOETZ AND MAURICE F. HASLER	1752

THE PHYSICAL REVIEW

A NOTE ON THE SPECTRA OF DOUBLY AND TREBLY IONIZED LEAD

BY STANLEY SMITH
UNIVERSITY OF ALBERTA
(Received May 27, 1930)

ABSTRACT

In the spectrum of Pb III three new singlet terms *viz.* $6s7s^1S_0$, $6s7p^1P_1$ and $6s7d^1D_2$ have been found to give rise to seventeen new lines which are here reported.

Certain discrepancies between the classification of terms by A. S. Rao and A. L. Narayan and the writer are discussed.

In the spectrum of Pb IV the previously published classifications of lines by J. A. Carroll, A. S. Rao and A. L. Narayan are discussed, and certain anomalies are pointed out. Two schemes different in some respects from those already put forward are suggested.

SPECTRUM OF Pb III

THE spectrum of Pb III has been discussed in several papers^{1,2,3} published during the past two years. The investigation of this spectrum has been continued by the writer and has led to the identification of three more singlet terms, which have been classified as $6s7s^1S_0$, $6s7p^1P_1$ and $6s7d^1D_2$. In the meanwhile a further paper by A. S. Rao and A. L. Narayan⁴ has appeared in which there is agreement with the writer with regard to the $6s7p^1P_1$ term but disagreement as to the identity of the term classified by the writer as $6s7s^1S_0$. As there are also further discrepancies between the results it was thought that it would be of interest to discuss these and to bring the information with regard to this spectrum up to date by adding a list of the new combinations which have been classified.

The data used in this investigation are the vacuum spark measurements of Mack,⁵ of R. J. Lang (unpublished) and of the writer.⁶ Spectrograms of the Schüler lamp discharge in the region from 1900Å to 7000Å obtained by the writer have also been found to be useful in this work. The writer is also

⁶ S. Smith, Trans. Roy. Soc. Canada 22, 331 (1928).

indebted to Dr. Lang for a plate of this spectrum taken on his vacuum spectrograph in the region 1300A to 2200A.

The two main points of disagreement between the classification of Rao and Narayan and that of the writer are in connection with the $6s7d^3D_{1,2,3}$ and $6s6d^1D_2$ terms. With regard to the $6s7d^3D_{1,2,3}$ terms Rao's choice does not lead to any observed lines in the predicted positions for the $6s6p^3P_{0,1,2} - 6s7d^3D_{1,2,3}$ combinations, whereas the terms selected by the writer do give fairly close agreement between predicted and observed lines for these combinations. Moreover the observed lines $\lambda\lambda 4094, 4128$, which apparently arise from combinations between $6s7d^3D_{1,2}$ and the newly found term $6s7p^1P_1$, may be considered as further evidence in support of the validity of the writer's choice of the $6s7d^3D_{1,2,3}$ terms. Turning now to the term $\nu = 104998$, classified by Rao as $6s6d^1D_2$ and by the writer as $6s7s^1S_0$, it will be noted that Rao gives $\lambda\lambda 4272, 4496$ as the combinations between this term and $6s7p^1P_1$ and $6s7p^3P_2$ respectively. If this classification is correct then the inner quantum number of the term in question clearly cannot be 0. However it is found that the wave-number difference between $\lambda\lambda 4272, 4496$ is 1163.6 whereas the value of $6s7p^3P_2 - 6s7p^1P_1$, deduced from the appropriate combinations using measurements in a region where the wave-lengths are known to a fairly high degree of accuracy, is 1158.4. This is so large a discrepancy that it throws doubt on the above mentioned classification of $\lambda\lambda 4272, 4496$. It is possible that $\lambda 4496$ is a $6s6d^3D$ combination as this line differs in wave-number from the line $\lambda 4400$, which also appears to be a line of doubly ionized lead, by 481.6. This is the value of the $6s6d^3D_{1,2}$ separation. The $6s6d^1D_2$ term has been previously given by the writer and $\lambda 3951$ appears to be the combination between this term and the newly found $6s7p^1P_1$ term and not an FG combination as classified by Rao. The lines $\lambda\lambda 2948, 3451$, given by Rao as $6s7p^3P_{1,2} - 6p7p^3P_2$ appear with considerable intensity on the Schüller lamp plates and are therefore to be attributed to Pb II.

The lines involving the new terms are given in Table I.

SPECTRUM OF Pb IV

The first investigation of this spectrum was made by Carroll,⁷ who gave the $6s^2S_1-6p^2P_{1,2}$ doublet, two of the $6d^2D_{2,3}-5f^2F_{3,4}$ triplet, and two choices for the $6p^2P_{1,2}-6d^2D_{2,3}$ triplet, the first of which included the line $\lambda 1069$, which has since been shown to be a Pb III line. An extension of this spectrum based on Carroll's identifications has recently been published by Rao and Narayan,⁸ but their classification does not appear to be a very probable one. The lines $\lambda\lambda 3909, 3279, 3089$, selected in Rao's scheme have been found to belong to Pb III. $\lambda\lambda 1726, 1796$ chosen by Carroll and by Rao as two of the $6d^2D_{2,3}-5f^2F_{3,4}$ triplet are found as very strong lines on the Schüller lamp spectrogram and therefore, in all probability, are to be attributed to Pb II. The writer has attempted to make a more probable selection, and a tentative scheme based on Carroll's second choice for the diffuse triplet is presented in Table II.

2508.98	2	39844.8	8063.5	$7p^2P_1-7d^2D_2$
3087.10	4	32383.5		$7p^2P_2-7d^2D_3$
3145.60	2	31781.3	602.2	$7p^2P_2-7d^2D_2$

* Selected by Carroll.

An alternative classification of the triplets involving $6d^2D_{2,3}$ terms in which these terms are inverted, as in the case of the doublet D terms of Pb II,⁹ is given in Table III. In these tables the wave-lengths are expressed in I.A._{air} above 2000Å and in I.A._{vac} below 2000Å. Mack's measures are used for the $6P-6D$ triplet in Table III.

TABLE III. *Alternative classification of lines of Pb IV.*

λ , Å.	Int.	ν	$\Delta\nu$	Classification
*890.78	5	112261		$6p\ ^2P_1 - 6d\ ^2D_2$
1096.47	2	91202	21059	$6p\ ^2P_2 - 6d\ ^2D_2$
*1116.09	7	89598	-1604	$6p\ ^2P_2 - 6d\ ^2D_3$
2864.54	7	34899.4		$6d\ ^2D_3 - 7p\ ^2P_2$
3002.78	2	33292.8	-1606.6	$6d\ ^2D_2 - 7p\ ^2P_2$
3962.45	6	25229.8	8063.0	$6d\ ^2D_2 - 7p\ ^2P_1$

* Selected by Carroll in his first choice of the diffuse triplet.

The fundamental triplet has not been found in either scheme and the $7p\ ^2P_{1,2}$ separation is larger than might be expected.

In conclusion I wish gratefully to acknowledge a grant from the National Research Council of Canada, which has been of assistance in this work.

THE SPARK SPECTRUM OF COBALT, Co II

By J. H. FINDLAY

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received May 19, 1930)

ABSTRACT

A further examination of the Co II spectrum, based on the previous work of Meggers, has been made. A magnetic analysis shows that Meggers' classification of the terms now called $d^7p\ ^5F^\circ$, $^5D^\circ$ should be interchanged, except for the term $^5F_5^\circ$. Since Meggers' results were obtained from intensity rules, the author's $^5F\ ^5F^\circ$ and $^5F\ ^5D^\circ$ multiplets show irregular intensities. The strongest lines in these multiplets are, respectively, $^5F_n\ ^5F_{n-1}^\circ$ and $^5F_n\ ^5D_n^\circ$. The magnetic analysis also shows that Meggers' terms 3D should be $d^7s\ ^5P$ and that his 3P , $^3D^1$, and 3F should be partly $d^7p\ ^5P^\circ$ and $^5D^\circ$. In addition, the terms $d^7s\ ^3F$, $d^7p\ ^3D^\circ$, $^3F^\circ$, $^3G^\circ$, $^5S^\circ$, $^5P^\circ$, $^5D^\circ$, and the lowest terms $d^8\ ^3F$ have been found. The location of the second member of the $d^7s\ ^5F\ ^3F$ series gives an I. P. of 16.9 volts from d^7s to d^7 and 17.3 volts from d^8 to d^7 , in practically exact agreement with the predictions of Dr. H. N. Russell.

INTRODUCTORY REVIEW

A PREVIOUS analysis of the first spark spectrum of cobalt was made by Meggers.¹ The purpose of the author's work was to extend Meggers' analysis with the aid of the Zeeman effect. The magnetic analysis afforded a change in the interpretation of several of Meggers' levels, and several new levels were found by the usual method of wave-number differences.

EXPERIMENTAL PROCEDURE

The author was fortunate in having the use of unpublished measurements and intensity estimates in the region from $\lambda 5000$ to $\lambda 2000$ made by Dr. Meggers of the Bureau of Standards. Further measurements were also made by the author of sharp lines in the range from $\lambda 2000$ to $\lambda 1940$ and of diffuse lines from $\lambda 3000$ to $\lambda 2550$, the standards being the copper arc and spark lines calculated by Shenstone.² Meggers' measurements were corrected to agree with these standards.

A Hilger E1 quartz spectrograph was used with Cramer Contrast and Hilger Schumann plates in taking photographs for wave-length determinations, sheets of very pure cobalt serving as electrodes.

Zeeman effect photographs were taken from $\lambda 3700$ to $\lambda 2190$ with the same instrument and an electromagnet, giving a field of about 35,500 gauss with pole pieces 1 cm in diameter and an air gap of about 3 mm. A button of cobalt about 1 mm thick clamped against one of the pole pieces of the magnet served as the anode, and a copper rod with a small tip on the end bent at right angles to the rest of the rod was used as the cathode of an arc, carrying a current of about 1 ampere at 250 volts, in taking most of the

Zeeman effect photographs, the exposures of which were from 5 to 15 minutes. A blast of nitrogen blowing over the arc kept the cobalt from burning away too rapidly and, hence, made the arc run more steadily. Under these conditions, most of the lines appearing on the Zeeman effect plates were cobalt spark lines. However, in the region from $\lambda 3700$ to $\lambda 3000$ a spark discharge had to be used as a light source to bring out the spark lines. A few copper lines appeared on the plates. Of these $\lambda 3273.97$ ($^3S_{\frac{1}{2}} - ^2P_{\frac{1}{2}}$), $\lambda 2441.63$ ($^3S_{\frac{1}{2}} - ^4P_{\frac{1}{2}}$), and $\lambda 2181.71$ ($^2S_{\frac{1}{2}} - ^2P_{\frac{1}{2}}$) were used to determine the field. A quartz double image prism separated the parallel and perpendicular components of the patterns.

TERM DESIGNATION

The Hund theory predicts that the low terms should be 3F from the structure $3d^8$, and $^3\&^5F$, $^3\&^5P$, etc. from the structure $3d^74s$. The middle terms should be the $^3\&^5S^0$, P^0 , D^0 , F^0 , G^0 , etc. from $3d^74p$. Many of these terms have been discovered and are given in Table I together with the $^3\&^5F$ from $3d^75s$. The notation used is that recommended by H. N. Russell, A. G. Shenstone, and L. A. Turner.³

ZEEMAN EFFECT

Several resolved patterns were obtained on the Zeeman effect photographs. Table II gives both the observed and calculated arrangement of these patterns. However, most of the lines appeared as simple triplets due to the low resolving power of the instrument. Nevertheless, a formula described by Shenstone and Blair⁴ allowed the calculation of g -values from the unresolved patterns. The g 's calculated from all the resolved and unresolved patterns are consistent with the assumption that all the terms have Landé g -values.

The magnetic analysis readily indicated that Meggers' classification of the 5F and $^5D'$ terms should be interchanged except for 5F_5 , his 3D terms should be $4s^5P$, and his 3P , $^3D'$, and 3F should be partly $d^7p^5P^0$ and $^5D^0$.

Since Meggers' results were based on intensity rules, the author's $4s^5F_4p^5F^0$ and $4s^5F_4p^5D^0$ multiplets show the irregular intensities indicated in Table III. In the case of spectra in which the Russell-Saunders coupling is broken down, there are usually irregular intensities, the g -values depart from Landé values, and the interval rule is not obeyed. In this spectrum, however, the interval rule is obeyed fairly well, and the terms have Landé g -values, yet two of the three principal multiplets show very anomalous intensities.

TABLE III. Intensities in the principal multiplets.

	$4s^5F_5$	5F_4	5F_3	5F_2	5F_1
$4p^2^5D_4^0$	25	80	10		
$^5D_3^0$		40	60	15	
$^5D_2^0$			30	30	10
$^5D_1^0$				30	25
$^5D_0^0$					20
$^5F_5^0$	100	10			
$^5F_4^0$	100	40	10		
$^5F_3^0$		80	40	10	
$^5F_2^0$			50	25	10
$^5F_1^0$				40	20
$^5G_5^0$	100				
$^5G_4^0$	8	75			
$^5G_3^0$	2	15	50		
$^5G_2^0$		3	20	40	
			4	15	30

IONIZATION POTENTIALS

The limits of the $4s^5F$, 3F series were determined by the application of a Rydberg formula to the two members of these series. However, on account of the inaccuracy of a Rydberg formula, this calculation did not, as is to be expected, give any indication of the four separate limits approached by the eight series.

The limit of the $4s^5F_5$ series gives an ionization potential of 16.9 volts from $3d^74s$ to $3d^7$, and 17.3 volts from $3d^8$ to $3d^7$. Using H. N. Russell's⁵

THE SPECTRA OF GASES LIGHTED WITH STRONG ELECTRICAL DISCHARGES*

BY E. O. HULBURT

NAVAL RESEARCH LABORATORY

(Received May 20, 1930)

ABSTRACT

Spectra of condensed discharges through hydrogen at pressures up to several cm of mercury showed, as usual, the Balmer lines merging into the continuous spectrum. With increasing strength of the discharge the Balmer lines widened, the higher members of the series disappeared and the continuous spectrum became more intense, until with 1 microfarad at 15 kilovolts there were no Balmer lines left at all, only the continuous spectrum and some absorption lines due to aluminum from the electrodes, etc. Helium, oxygen and nitrogen exhibited similar changes, i.e., with increasing intensity of the discharge in helium the lines gave way to a continuous spectrum, and in oxygen and nitrogen the molecular bands gave way to spark lines and these in turn to a continuous spectrum. The continuous spectra from all the gases were alike. The intensity distribution across the continuous spectrum was rather even and hardly that of a black body. In the strong discharges the external characteristics of the atoms were pretty well effaced and the conditions perhaps approached those in the interior of a star.

IT IS known that the spectrum of a gas varies with the pressure of the gas and with the type of electrical excitation, for example, the Balmer lines of hydrogen broaden with increasing pressure and intensity of the discharge. The experiments described in this paper were undertaken to find out what the spectrum of the gas is like when very strong discharges are used.

Fig. 1. Apparatus for sending strong discharges through the tube *D*.

A discharge tube *D*, Fig. 1, was arranged to be excited either directly by a 15000 volt, 25 cycle transformer *T*, or by a 0.002 microfarad condenser in series with a quenched gap to insure abrupt discharges, or by a 1 microfarad condenser. Fig. 1 gives a diagram of the apparatus for the last case.

* Published with the permission of the Navy Department.

With the switch *S* in position 1 the transformer *T* charged the condenser *C* through the rectifier *R*. When the switch was thrown quickly to position 2 by means of a spring the condenser discharged through the tube *D*. The arrangement was essentially that used by Anderson in his experiments with exploded wires.¹ The discharge tube was of glass with aluminum electrodes, the bulbs around the electrodes being about 5 cm in diameter. Sections *ab* and *cd* were 6 cm in length and *bc* was 7 cm in length and of internal diameter less than 1 cm. The light coming end-on through the quartz window *W* was photographed with a small quartz spectrograph. The discharge of the 1 microfarad condenser through the tube produced a blinding flash of light

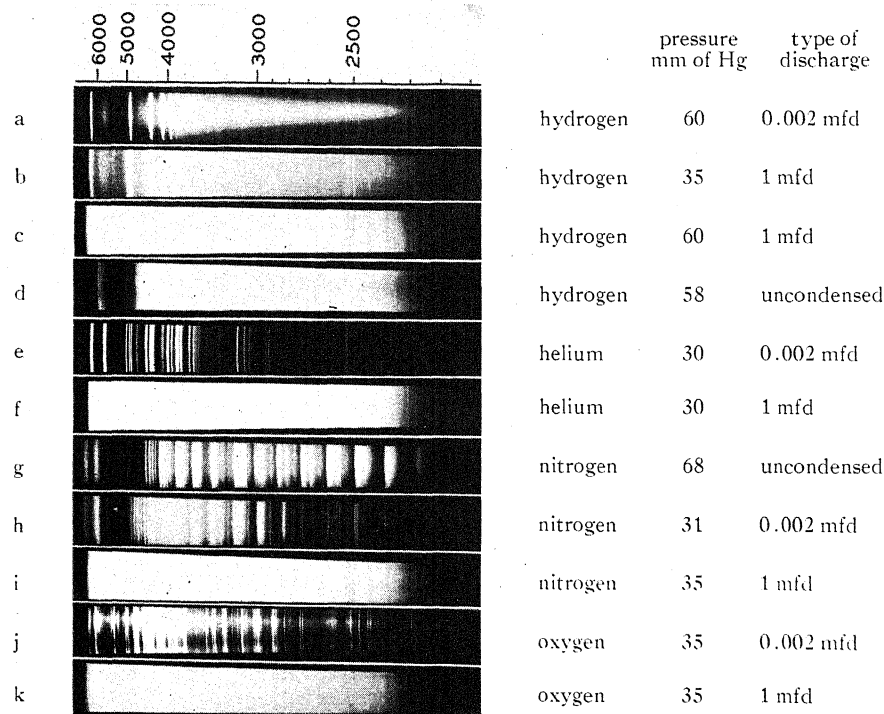

Fig. 2. Spectra of gases under various types of discharge.

and a fairly loud crack of sound, not so loud perhaps as the noise of an exploded wire. Usually a single discharge was sufficient to record the spectrum down to $\lambda 2000\text{\AA}$ in the ultra-violet. The pressure pulse in the tube sometimes blew off the quartz window, which was sealed on with wax. After a considerable number of discharges there were many fine superficial cracks on the interior surface of the portion *abcd* of the tube. None of the tubes, however, were broken by the violence of the discharge.

Some of the spectra of hydrogen, helium, nitrogen and oxygen are given in Fig. 2. Using the 0.002 microfarad condenser discharge the Balmer lines

¹ Anderson, *Astrophys. J.* **51**, 37 (1920); Smith *Astrophys. J.* **61**, 186 (1925); Anderson and Smith, *Astrophys. J.* **64**, 295 (1926).

of hydrogen widened with increasing pressure, as in strip *a* Fig. 2, the members of the series below H_γ disappeared and the continuous spectrum increased in intensity. With the 1 microfarad condenser and a discharge tube of 8 mm internal diameter between *b* and *c*, Fig. 1, there were only four Balmer lines left, these being much widened, and the continuous spectrum was intense, as in strip *b*. With the 1 microfarad condenser and a discharge tube of 4 mm internal diameter between *b* and *c*, Fig. 1, there were no Balmer lines left at all, only the continuous spectrum, as in strip *c*. The continuous spectrum was crossed by a few absorption and emission lines. Most of these were aluminum lines, but not all of them were identified. The spectra with the 1 microfarad condenser discharges were much the same for gas pressures from 20 to 60 mm of mercury, as might be expected on the idea that under such violent excitation the momentary pressure in the path of the discharge was very high and not dependent to a great extent on the pressure of the cold gas. Pressures greater than about 80 mm of mercury could not be used, for at greater pressures the discharge would not pass through the tube with the potentials available. It is interesting to compare strip *c* with strip *d* which is the spectrum of an uncondensed discharge through hydrogen at a pressure of 58 mm of mercury. This appears, except for its weakness at wave-lengths greater than 5000Å, much like strip *c*. The conditions of excitation of the gas for the two spectra were as different as could well be imagined, the one being a brilliant flash and the other a gentle blue glow, and yet the continuous spectra are somewhat similar.

Helium, nitrogen and oxygen, strips *e* to *k*, Fig. 2, exhibited changes similar to those of hydrogen, i.e. with increasing intensity of the discharge in helium the lines gave way to a continuous spectrum, and in oxygen and nitrogen the molecular bands gave way to spark lines and these in turn to a continuous spectrum. The continuous spectra from all the gases with the 1 microfarad condenser discharge were closely alike. A comparison with the lines of a mercury spectrum whose intensities were known² showed that the distribution of intensity across the continuous spectra was constant within two, and probably one, orders of magnitude from $\lambda 6000$ to 2000\AA . Thus, within the fairly large error of measurement, the intensity distribution did not seem to be that of a black body.

The general result of the experiments appeared to be that under the strong discharges the external characteristics, such as energy levels, etc., of the atoms of the gases were pretty well effaced. The atoms could no longer radiate their usual line or band spectrum but only a continuous spectrum. We may imagine that the conditions approached those in the interior of a star. It seems difficult at the present time to form a satisfactory quantitative theory of the continuous spectrum. In trampling on the atom we have at the same time trampled on theories of atomic behavior. It is hoped to extend the investigation using greater dispersion.

COMPUTATION OF THE EFFECTIVE CROSS SECTION FOR THE RECOMBINATION OF ELECTRONS WITH HYDROGEN IONS

BY E. C. G. STUECKELBERG AND PHILIP M. MORSE
PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received May 16, 1930)

ABSTRACT

The quantum-mechanical computation of the cross-section for combination of electrons with a positive point charge has been carried out in polar coordinates. This gives the fraction of the recombination to a final state of total quantum number n arising from recombination to the substates of different l values, making possible a comparison of the results with the experimental recombination intensities for alkali vapors to which the theory applies approximately.

AN ELECTRON passing by a hydrogen ion with a velocity equivalent to V volts can undergo a spontaneous transition to one of the states of a hydrogen atom. The probability with which such a process can occur has been treated by Kramers¹ and by Eddington² by the methods of the old quantum theory and the correspondence principle. Oppenheimer³ gives in his treatment of the motion of electrons in a Coulomb field the corresponding wave-mechanical expressions. The following paper gives certain additional calculations and numerical expressions for the probability of capture of electrons.

We recall the definition of the effective cross section of recombination: The decrease of the number N_+ ions per cm^3 is expressed by

$$\frac{dN_+}{dt} = -\alpha(v) \cdot N_+ \cdot N_- = -q(v) \cdot N_+ \cdot N_-' \quad (1)$$

N_- is the number of electrons per cm^3 having a velocity v relative to the ions. $N_-' = v \cdot N_-$ is the intensity of a stream of N_-' electrons per cm^2 per sec. $\alpha(v)$ is called the coefficient of recombination and $q(v)$ the effective cross section of recombination.

To find the probability of a transition of such an electron to one of the discrete states with negative energy one computes first the matrix element of the electric moment associated with the transition under consideration. As wave function in the initial state we require a solution $\psi_k(r, \cos \theta, \phi)$ of the wave equation in the force field of an ion of charge $Z \cdot e$, which becomes a plane wave at infinite distance, representing a stream along the x axis of N_-' electrons per cm^2 per sec.:

$$\lim_{r \rightarrow \infty} \psi_k = C \cdot \left\{ e^{i(Z/k a_0)x} + \frac{f(\cos \theta)}{r} \cdot e^{i(Z/k a_0)r} \right\} \quad (2)$$

¹ Kramers, Phil. Mag. 46, 836 (1923).

² Eddington, Internal Constitution of Stars, Cambridge (1926).

³ Oppenheimer, Zeits. f. Physik 55, 725 (1929).

and

$$\lim C \cdot \frac{h}{2\pi mc} \cdot \text{imag} (\bar{\psi}_k \text{grad } \psi_k) = N_-'$$

$$k^2 = \frac{R_V Z^2}{V} \quad (3)$$

V is the energy of the electrons and R_V is the ionization energy of a hydrogen atom in volts. a_0 is the radius of the first Bohr orbit in hydrogen. In the final state we take the known solution of the wave equation in polar coordinates $\psi_{n,l,m}(r, \cos \theta, \phi)$. Then we compute the matrix elements in the complex rectangular coordinates

$$\left. \begin{aligned} x &= r \cos \theta; & X^2(k, nlm) \\ u &= r \sin \theta \cdot e^{i\phi}; & U^2(k, nlm) \\ v &= r \sin \theta \cdot e^{-i\phi}; & V^2(k, nlm) \end{aligned} \right\} = \int \frac{x}{u} \bar{\psi}_k \psi_{nlm} d\tau_x \int \frac{x}{v} \bar{\psi}_k \psi_{nlm} d\tau \quad (4)$$

$$d\tau = \rho^2 \sin \theta d\rho d\theta d\phi$$

The relation between the matrix element $X(k, nlm)$ and the number of transitions per sec $q_x(k, nlm)$ N_-' giving light of frequency ν_n polarized in the x direction is

$$q_x(k, nlm) \cdot N_-' = \frac{64\pi^4}{3} \cdot \left(\frac{\nu_n}{c}\right)^3 \frac{\{\epsilon \cdot X(k, nlm)\}^2}{h} \quad (5)$$

Similar expressions hold for u and v . The total cross section for any given state n, l is

$$\begin{aligned} q(k, nl) &= q_x(k, nl0) + q_u(k, nl-1) + q_v(k, nl+1) \\ &= q_x + 2q_u. \end{aligned}$$

Oppenheimer⁴ computed by this method the $q(k, 10)$ and showed that it is asymptotically, for small velocities of the electron, proportional to Z^2/V . In a later paper he treated the problem for the excited states in parabolical coordinates⁵ using a wave function by Gordon⁵ and Temple,⁶ which satisfies Eq. (2). This method gives the expression of the total cross section summed over all l 's with the same n . The writers made use of the wave function used by Mott⁷ for the scattering of α -particles by nuclei in order to obtain the individual $q(nl)$'s. Mott's formula is in this notation:

$$\psi_k = i \cdot \left(\frac{N_-' \cdot h}{2\pi Z \epsilon^2}\right)^{1/2} \cdot \frac{k^{1/2} \cdot e^{(k\pi/2) + ik \log \rho}}{\sinh \pi k} \quad (6)$$

$$\sum_{\lambda=0}^{\infty} \frac{i^\lambda \cdot (\lambda + \frac{i}{2}) \cdot P_\lambda(\cos \theta)}{\Gamma(\lambda + 1 + ik)} \cdot \rho^\lambda \cdot \oint e^{\rho z} \cdot \left(z - \frac{i}{2}\right)^{\lambda-ik} \cdot \left(z + \frac{i}{2}\right)^{\lambda+ik} \cdot dz$$

⁴ Oppenheimer, Phys. Rev. **31**, 349 (1928).

⁶ Temple, Proc. Roy. Soc. **121A**, 673 (1928).

⁷ Mott, Proc. Roy. Soc. **118A**, 542 (1928).

$\rho = (2Z/ka_0) \cdot r$ and the integral is to be taken along a single contour around $z = \pm i/2$. The asymptotic expansion for $r = \infty$ satisfies Eq. (2), having however in the first exponent an additional slowly varying logarithmic term (see Oppenheimer⁴ and Mott⁷). The evaluation of the integrals in Eq. (4) is done following a method given by Fues⁸ and used for similar problems by Oppenheimer.⁹ At one step one is left with an integral

$$J(k) = \oint \frac{\left(z - \frac{i}{2}\right)^{\lambda - ik} \left(z + \frac{i}{2}\right)^{\lambda + ik}}{\left(-z + \frac{k}{2n}\right)^{l + \lambda + s + 4}} dz$$

to be taken around $z = k/2n$. Its evaluation leads to the formulas 7a and 7b. for $q_z(nl)$ and $q_u(nl)$. 7c and 7d are the formulas taken from Oppenheimer's paper.³

Abbreviating: R for the Rydberg constant in frequency units

$$Q(\lambda, \alpha) = \sum_{p=0}^{p=\alpha} \binom{\lambda - ik}{p} \binom{\lambda + ik}{\alpha - p} \left(\frac{n + ik}{-n + ik}\right)^{(\alpha/2) - p},$$

$$S(k, l) = \frac{k^{2l+6}}{k^2(k^2 - 1^2)(k^2 - 2^2) \dots (k^2 - (l-1)^2)},$$

$$T(k) = \frac{e^{\pi k - 4k \tan^{-1}(n/k)}}{\sinh \pi k},$$

$$D = \frac{32 \cdot \pi^5 \cdot a_0^5 R^2}{3 \cdot Z^2 c^2}$$

$$F(\alpha \beta \gamma) = 1 + \frac{\alpha \cdot \beta}{1 \cdot \gamma} \cdot z + \frac{\alpha(\alpha + 1) \cdot \beta(\beta + 1)}{1 \cdot 2 \cdot \gamma(\gamma + 1)} z^2 + \dots$$

$$q_z(n, l) = D \cdot \frac{\nu_n}{c} \cdot \frac{(n - l - 1)!}{(2l + 1) \cdot (n + l)! n^{2l+4}} \cdot S(k, l) \cdot T(k)$$

$$\cdot \left\{ \sum_{s=0}^{s=n-l-1} \left(\frac{2}{n}\right)^s \cdot \left(\frac{R \cdot Z^2}{\nu_n}\right)^{s/2} \cdot \frac{(2l + 2 + s)!}{s!} \binom{n + l}{n - l - 1 - s} \right. \\ \cdot \left[\frac{4l}{k^2} \frac{RZ^2}{\nu_n} \cdot Q(l - 1, 2l + 2 + s) - \frac{(2l + s + 3)(2l + s + 4)(l + 1)}{(l + ik)(l + 1 + ik)} \right. \\ \left. \left. \cdot Q(l + 1, 2l + 4 + s) \right] \right\}^2 \quad (7a)$$

⁸ Fues, Ann. d. Physik **81**, 422 (1926).

⁹ Oppenheimer, Zeits. f. Physik **41**, 268 (1927).

$$q_u(n, l) = q_v(n, l) = D \cdot \frac{\nu_n}{c} \cdot \frac{(l+1)!(n-l-1)!}{(l-1)!(2l+1) \cdot (n+l)!n^{2l+4}} S(k, l) \cdot T(k) \cdot$$

$$\left\{ \sum_{s=0}^{s=n-l-1} \left(\frac{2}{n} \right)^s \left(\frac{R \cdot Z^2}{\nu_n} \right)^{s/2} \cdot \frac{(2l+2+s)!}{s!} \binom{n+l}{n-l-1-s} \right\} \quad (7b)$$

$$\left[\frac{4}{k^2} \cdot \frac{RZ^2}{\nu_n} O(l-1, 2l+2+s) + \frac{(2l+s+3)(2l+s+4)}{(l+ik)(l+1+ik)} \cdot Q(l+1, 2l+4+s) \right]$$

$$q_z(n) = \sum_{l=0}^{l=n-1} q_x(n, l) = 64D \cdot \frac{\nu_n}{c} \cdot \frac{k^6}{(n^2 + k^2)^2} \cdot T(k)$$

$$\sum_{s=0}^{s=n-1} \left| (n-s-1) \cdot F\left(-ik, 2+s-n, 1, \frac{-4ink}{(n+ik)^2}\right) \right. \quad (7c)$$

$$\left. - \left(n-s-1 - \frac{2ink}{n+ik} \right) F\left(-ik, 1+s-n, 1, \frac{-4ink}{(n+ik)^2}\right) \right|^2$$

$$q_u(n) = q_v(n) = \sum_{n=0}^{n=l-1} q_u(nl) = 64D \cdot \frac{\nu_n}{c} \cdot \frac{(4n)^2 k^{10}}{(n^2 + k^2)^4} \cdot T(k). \quad (7d)$$

$$\sum_{s=0}^{s=n-2} (s+1)(n-s-1) \left| F\left(1-ik, 2+s-n, 2, \frac{-4ink}{(n+ik)^2}\right) \right|^2.$$

For electrons whose kinetic energy is small compared with the term value of the final state, we substitute $w=z/k$ in the integral $J(k)$ and obtain

$$J(k) = k^{\lambda-l-s-3} \oint \frac{w^{2\lambda} \cdot e^{-1/w} \cdot dw}{\left(-w + \frac{1}{2n}\right)^{l+\lambda+s+4}}.$$

This integral is to be taken around the point $w=1/2n$ and is independent of k . Instead of formulas 7a and 7b we obtain 8a and 8b. 8c and 8d are the corresponding asymptotic expressions for $k=\infty$ of Eq. (7c) and (7d). For all states we obtain $q=A \cdot 10^{-20} \cdot Z^2/V$ for small V . Since in experiments on recombination the electron velocities are usually small, these formulas are sufficient in most cases.

Abbreviating

$$K(t, \lambda) = \sum_{\alpha=0}^{\alpha=t} \binom{t}{\alpha} \binom{2\lambda}{\alpha} \frac{\alpha!}{(2n)^\alpha} \cdot \sum_{\beta=0}^{\beta=t-\alpha-1} \binom{t-\alpha}{\beta} \binom{t-\alpha-1}{\beta} \frac{\beta!}{(-2n)^\beta}$$

$$E = \frac{4^7 \cdot \pi^5}{3c^3} \cdot a_0^5 R^3 R_v = 1.24 \times 10^{-19} \text{ cm}^2 \text{ volt}$$

$$M(t, \lambda) = \sum_{\alpha=0}^{\alpha=t} \binom{t}{\alpha} \frac{(-4n)^\alpha}{(\alpha + \lambda)!}$$

we obtain

$$q_x(nl) \sim \frac{E \cdot Z^2}{V} \cdot \frac{(n-l-1)! 16^l \cdot n^{2l+2}}{(2l+1) \cdot (n+l)! e^{4n}} \quad (8a)$$

$$\left\{ \sum_{s=0}^{s=n-l-1} \frac{(4n)^s}{s!} \binom{n+l}{n-l-s-1} [l \cdot R(2l+s+2, l-1) + (l+1) \cdot R(2l+s+4, l+1)] \right\}^2$$

$$q_u(nl) = q_v(nl) \sim \frac{EZ^2}{V} \cdot \frac{l(l+1) \cdot (n-l-1)! 16^l \cdot n^{2l+2}}{(2l+1) \cdot (n+l)! e^{4n}} \cdot \left\{ \sum_{s=0}^{s=n-l-1} \frac{(4n)^s}{s!} \binom{n+l}{n-l-s-1} [K(2l+s+2, l-1) - K(2l+s+4, l+1)] \right\}^2 \quad (8b)$$

$$q_x(n) = \sum_{l=0}^{l=n-1} q_x(n, l) \sim \frac{EZ^2}{V} \cdot \frac{1}{4n^2 \cdot e^{4n}} \cdot \sum_{s=0}^{s=n-1} \{ (n-s-1) \cdot M(n-s-2, 0) + (n+s+1) \cdot M(n-s-1, 0) \}^2 \quad (8c)$$

$$q_u(n) = q_v(n) = \sum_{l=0}^{l=n-1} q_u(n, l) \sim \frac{E \cdot Z^2}{V} \cdot \frac{4}{e^{4n}} \cdot \sum_{s=0}^{s=n-2} (s+1) \cdot (n-s-1) \cdot M(n-s-2, 1)^2. \quad (8d)$$

Empirical formulas are generally written in a form

$$q(n, l) = \text{const} \times \frac{1}{V \cdot \nu_{nl}^s}, \quad (9)$$

where ν_{nl} is the frequency of the emitted light, given for hydrogen by

$$\nu_{nl} = \nu_n = RZ^2 \left(\frac{1}{n^2} + \frac{1}{k^2} \right). \quad (10)$$

$s=2$ for the $2P$ band of Cs I (see report on recombination by Mohler¹⁰). Evaluating Eq. (8) for some of the lower states and abbreviating the algebraic expressions of k in frequencies according to Eq. (10) one obtains formulas 11, where

$$B = \frac{2 \cdot 4^6 \cdot \pi^5}{3} \cdot \frac{a_0 \cdot R^5 \cdot R_p \cdot Z^6}{c^3}.$$

¹⁰ Mohler, Phys. Rev. Supplement 1, 216 (1929).

$$\begin{cases}
 1s: q = q_x(10) = B \cdot T(k) \cdot \frac{1}{V \cdot \nu_1^2} \\
 2s: q = q_x(20) = \frac{B \cdot T(k)}{8} \cdot \frac{\nu_1}{V \cdot \nu_2^3} \\
 3s: q = q_x(30) = \frac{B \cdot T(k)}{27} \cdot \frac{\nu_1 \cdot \nu_2^2}{V \cdot \nu_3^5}; i = \left(\frac{27}{7}\right)^{1/2} \sim 2 \\
 2p: q = q_x(21) + 2q_u(21) = B \cdot T(k) \cdot \frac{RZ^2 \left(\frac{1}{36} \frac{\nu_j}{\nu_2} + \frac{1}{8} \right)}{\nu_2^3}; \\
 \quad j = \frac{2}{3}
 \end{cases} \quad (11)$$

This shows that the empirical way of writing the formulas involves frequency terms without physical meaning. The general form of the expressions (11) however is similar to Eq. (9), as T varies only slowly with k . None of these functions shows any maximum point corresponding to the results of Davis and Barnes experiment,¹¹ nor do any of the curves for higher states.

From formulas 8a and 8b the constants $A(nl)$ were computed for some of the lower states. The complexity of the sums increases greatly with larger n 's. Fig. 1 compares the exact and the asymptotic expressions for the 1s

Fig. 1. Exact and asymptotic values of q for recombination to the 1s state.

state. Table I and Fig. 2 give the values of $A(n)$ for 1s, 2s, 2p, 3s, \dots , to 5s. The values of $\Sigma_l A(nl)$ is given in the last column of Table I and plotted as black dots in Fig. 2. The $\Sigma_l A(nl)$ have been computed by summing over the $A(nl)$ from Eq. (8a) and (8b), and to check it, also directly by Eq. (8c) and (8d). (Oppenheimer's formulas.)

For a comparison of the absolute magnitude of the q 's with the experimental values obtained from recombination spectra, we compare in Table II the values as given by Mohler¹⁰ for the $1S$, $2P$ and $3D$ states of caesium for $V=0.2$ volts with the states $2s$, $2p$, $3d$ of hydrogen. There is little justification for picking these hydrogen states as comparison, except that their

Fig. 2. Values of A in the formula $q = A \times 10^{-20} Z^2/V$ for recombination to various states.

effective quantum numbers most nearly correspond. For the P and D state we have a satisfactory agreement. The discrepancy of the $1S$ value is to be expected, since it is a highly penetrating orbit, and therefore would differ from a hydrogen-like behavior in a much greater degree than the P and D states. A similar disagreement is pointed out by Mohler¹⁰ in comparing the continuous absorption of these states with the theoretical computations for

TABLE II. Comparison of values of q for $V=0.2$ volts between caesium (experimental data) and hydrogen (theoretical data).

Cs		H	
term	q	term	q
1S	$0.015 \times 10^{-21} \text{ cm}^2$	2s	$1.7 \times 10^{-21} \text{ cm}^2$
2P	$6.0 \times 10^{-21} \text{ cm}^2$	2p	$5.5 \times 10^{-21} \text{ cm}^2$
3D	$6.0 \times 10^{-21} \text{ cm}^2$	3d	$2.6 \times 10^{-21} \text{ cm}^2$

the same hydrogen states by Oppenheimer.⁹ If one takes the states $6s$, $6p$ and $5d$ of hydrogen, whose *true* quantum numbers are the same as for the series electron of Cs in the considered states, the correspondence is improved with respect to the S -state (it being wrong by a factor 10 instead of 100) but the agreement for the P - and D -states is worse by a factor of about 10. This comparison is not given in Table II, because these higher terms have not been computed but only roughly extrapolated

It can not be expected to have any better agreement than this, since the wave function of the series electron in Cs is considerably different from that of any state in hydrogen. It is interesting to see that the best agreement for the P and D states is obtained by comparison with hydrogen states of the same effective quantum number.

Attempts to find an expression for the total target area

$$q = \frac{\sum_{n,l} A(nl) \times 10^{-20} \times Z^2}{V}$$

have not been successful.

The experiments by Davis and Barnes¹¹ can not be explained through spontaneous recombination of the electrons and α -particles and must therefore be due to some other mechanism.

THE RECOMBINATION OF IONS IN ARGON,
NITROGEN AND HYDROGEN

BY OVERTON LUHR

PHYSICAL LABORATORY, UNIVERSITY OF CALIFORNIA

(Received May 27, 1930)

ABSTRACT

Since free electrons are known to exist in ionized A, N₂ and H₂ these gases are employed in an effort to measure directly the coefficient of recombination for positive ions and electrons. At the same time the coefficient is determined for positive and negative ions in H₂ which would be expected theoretically to differ from other gases. The method is one using x-rays as the ionizing agent and has already been described by L. C. Marshall and the writer. Previous indirect methods and theory indicate that α , the coefficient of recombination for ions and electrons is of the order of 10^{-10} compared to 10^{-6} for positive and negative ions. In the present work results similar to those in air are obtained in the pure gases, and only a slight change in α is observed when sufficient O₂ is added to cause immediate attachment of the free electrons. Further direct tests in pure A, N₂ and H₂ indicate that negative ions are present in large quantities at all times, although a constant number of free electrons is also present. Hence it is probable that recombination was taking place between positive and negative ions rather than positive ions and electrons. It is assumed that as a result of the action of the ionizing agent negative ions are formed by attachment to excited metastable molecules in the case of A and N₂ and by attachment to atoms or triatomic molecules in the case of H₂.

In accordance with the criterion established in a previous paper for air, "absolute values" of α are set as follows:

Gas	Coefficient of Recombination
Air	$1.4 \pm 0.1 \times 10^{-6}$
O ₂	$1.5 \pm 0.1 \times 10^{-6}$
A	$1.2 \pm 0.1 \times 10^{-6}$
N ₂	$1.2 \pm 0.1 \times 10^{-6}$
H ₂	$0.32 \pm 0.05 \times 10^{-6}$

The results in H₂ show a constant value of $0.32 \pm 0.05 \times 10^{-6}$ which is much lower than in the other gases contrary to the prediction of the J. J. Thomson theory of recombination. However, the theory is deficient in certain respects which may explain this discrepancy.

INTRODUCTION

THE present work on the recombination of ions produced by x-rays is a continuation of previous investigations by L. C. Marshall¹ and the writer.² This second part was undertaken in an effort to measure directly the coefficient of recombination of positive ions and electrons, and at the same time to determine the coefficient of recombination in H₂ which would be expected to differ from other gases. Gases were used in which free electrons

¹ L. C. Marshall, Phys. Rev. 34, 618 (1929).

² O. Luhr, Phys. Rev. 35, 1394 (1930).

are known to exist for considerable periods of time. Thus in A, N₂ and H₂ free electrons will not attach to the normal molecules, but may attach to excited molecules or to molecules of impurity which may be present.

Theoretically it is to be expected that recombination between electrons and positive ions would proceed very slowly compared to that between negative and positive ions.³ This has in general been born out by numerous indirect spectroscopic methods of measurement⁴ and in one case by the direct measurements of Atkinson⁵ whose results, however, were inconclusive. Kenty,⁶ using spectroscopic methods and the Langmuir probe estimated the coefficient in very pure A to be of the order of 10^{-10} compared to 10^{-6} for positive and negative ions. Marshall,¹ with practically the same apparatus as that used by the writer believed he had found evidence of a low coefficient of recombination in pure A since the value was only about half that obtained when one cm partial pressure of O₂ had been added to the pure gas. The one cm of O₂ was sufficient to cause immediate attachment of all the free electrons present. Marshall used a metal ionization chamber where it is impossible to obtain the best conditions of purity, and he believed that the recombination in pure A was taking place principally between positive ions and negative ions formed by attachment of electrons to molecules of impurity.

In the present work it was found that Marshall's results were partially in error due to an unshielded lead (from the commutator to the ionization chamber) which caused a small statically induced charge to remain on the lower plate of the ionization chamber. No such effect was to be expected since the lead and lower plate were grounded through a half megohm resistance. However, because of the very high potentials in the room from the x-ray equipment, there was actually sufficient field to draw out most of the free electrons in 0.15 seconds, though there was no appreciable effect on the ions. Marshall attributed this loss of electrons to diffusion, but very little loss was observed in the present work even after a second, when the lead was shielded by enclosing it in a grounded metal tube. Also, the coefficient of recombination remained approximately the same when sufficient partial pressure of O₂ was added to any of the gases to obtain immediate attachment of the free electrons. This might indicate that the coefficient of recombination for positive ions and free electrons is nearly the same as for positive and negative ions, but it is believed that actually a considerable number of free electrons were attaching, possibly to impurities, but more likely to metastable excited molecules produced by the ionizing agent.

METHOD OF MEASUREMENT AND PRELIMINARY EXPERIMENTS

The apparatus has already been described by Marshall¹ and the writer,² and was used in exactly the same form in the present work. It consists of a rotating shutter and commutator mechanism which furnishes a means of

ionizing the gas in the ionization chamber by a flash of x-rays, then measuring the charge remaining at any time afterward by a suitable adjustment of the commutator and brushes. A sufficiently high field is applied to the lower plate of the ionization chamber through the commutator to produce a saturation current, thus sweeping all the ions of one sign to the upper plate almost instantly at any desired time. A neutralizing current is forced through a high resistance carbon line leak by means of a potentiometer, thus keeping the upper plate and electrometer system always at zero potential during the flash time and time of recombination.

The method of calculation is also the same as before, all values of α , the coefficient of recombination—obtained from the equation $\alpha = 1/t(1/n - 1/n_0)$ —being determined as a function of τ the age of the ions rather than t the total time of recombination.² In some cases this produced rather irregular results due to the very small differences in the potentiometer readings when the time of recombination was of the order of a few thousandths or a hundredth of a second. Thus very small errors in taking the potentiometer readings, due principally to fluctuations in intensity of the x-rays caused large errors in the values of α , and the plotted points do not always lie as close to a smooth curve as would be desired. However, since this method of calculation gives the only true picture of what is happening at any particular time, it was thought best to use it throughout.

Two small though important changes were made in the method of measurement. Instead of making use of the total volume of the ionization chamber ($10 \times 20 \times 7.5$ cm), the defining slit at the front of the chamber was narrowed down so that a beam of x-rays about 2.5 cm instead of 7.5 cm high passed between the plates. The volume of ionization was thus kept about 2.5 cm from each plate so that the possibility of diffusion of electrons to the plates with a resulting spuriously high coefficient of recombination would be at a minimum. On a kinetic theory basis it may be estimated that an electron would, on the average, diffuse a distance of two or three cm in as little as one-tenth of a second. However, this is extremely unlikely in the present case since the space charge produced by the positive ions remaining in the volume of ionization would prevent the electrons from diffusing to any great extent. Nevertheless, it was actually found in tests on A that the coefficient of recombination dropped off about fifteen percent as the distance of the x-ray beam from the plates was increased to a maximum.

The other change in the method of measurement consisted in having the sector opening the same for every run regardless of the commutator speed. This was necessary to produce sufficient ionization for convenient measurement. The sector opening was only 18° for A due to the intense ionization and 90° for air, N_2 and H_2 . Thus effectively older ions and more random distribution occurred at faster commutator speeds. Hence, α dropped more rapidly with time though the initial and final values remained the same as before, as shown by a comparison of the results in air obtained with the two methods. The situation was further aggravated by the high intensities of x-radiation which were necessary to produce sufficient ionization in H_2 and

N₂. As a result it is more difficult to set an "absolute value" for the coefficient of recombination as was done for air,² since the point at the end of the sharp drop due to nonrandom distribution is not clearly defined.

As in the previous work on air and O₂, all values of α are corrected for diffusion by assuming a swelling of the volume of ionization given by,

$$V = V_0 + 2A(\overline{\Delta x})_\tau$$

where V_0 is the initial volume, A is the area of the upper plate of the ionization chamber and $(\overline{\Delta x})_\tau$ is the average distance an ion will diffuse in time τ given by $(\overline{\Delta x})_\tau = (4D\tau/\pi)^{1/2}$ from the Brownian movement equation.⁷ D is the coefficient of diffusion given by $D = 0.0236k$ where k is the mobility of the ions. For air, A and N₂ the average mobility is about 2 cm per second per volt per cm, or D is 0.047. The mobility in H₂ is of the order of 6 cm per second giving D as 0.142. Owing to the use of a relatively small volume of ionization (though it was still 448 cm³ or seven times as large as that used by Marshall) the diffusion corrections were of the order of twenty percent at the longest time intervals but this correction gave results apparently consistent with the previous ones in air using larger volumes.

One extraneous effect observed in pure A, N₂ and H₂ is worthy of note. While Marshall was continually losing free electrons until there were very few left after 0.15 seconds, in the present work the negative readings were in general about three percent higher than the positive. This effect was evidently due to the presence of free electrons since the positive and negative readings became equal if sufficient O₂ was added to produce attachment. It was apparently not caused by a residual field as in Marshall's case since it was purely a percentage effect not varying with time. This possibility was further investigated by allowing x-rays to pass into the chamber with no field present to sweep out the ions. No appreciable charge was built up on the upper plate as long as the shielded lead was employed, but if the unshielded one used by Marshall was inserted a large positive charge accumulated indicating the loss of electrons to the lower plate. It was thought that possibly scattered radiation from the x-ray beam was in some way producing an excess of negative charges by photoelectric action on the metal surfaces, but photographs of the beam emerging from the ionization chamber showed it to be very sharply defined with no indication of any scattered radiation. The explanation may lie either in the presence of contact potentials or in a slight distortion of the field producing weak curved lines of force outside the volume of ionization which would sweep electrons of high mobility but not negative ions to the upper plate. The effect was not considered to be serious, however, since the positive readings were always used in calculating the coefficient of recombination. The negative readings would in general have given slightly higher values of α indicating a very small loss of electrons by diffusion from between the plates.

In regard to the purity of the gases, extreme care was taken so that the possibility of attachment of free electrons to molecules of impurity was

⁷ L. B. Loeb and L. C. Marshall, *Jour. Frank. Inst.* **207**, 371 (1929).

reduced to a minimum. The ionization chamber was thoroughly cleaned with cleaning solution to remove any organic materials. The A, N₂ and H₂ were first passed over copper heated to 400°C to remove the oxygen. They were then subjected to the same treatment as the air by passage through glass wool, sodium calcium hydrate, CaCl₂, P₂O₅ and two liquid air traps. The A, which was the purest obtainable in large quantities contained considerable N₂ as indicated by the presence of N₂ bands in the spectrum. Otherwise the gases were spectroscopically pure showing no evidence of organic compounds or oxygen when the discharge was observed with a large direct vision spectroscope.

Direct tests for the presence of free electrons. In view of the unexpectedly high values of α obtained in pure A, N₂ and H₂ it was thought desirable to test further for the presence of free electrons. In order to accomplish this a second brush was added to the commutator system so that an alternating potential could be applied to the lower plate of the ionization chamber. Thus by keeping the volume of ionization close to the lower plate and varying the driving and retarding potentials, the apparatus could be used to measure mobilities by the simple Rutherford alternating current method.⁸ Although the measurements were somewhat complicated by the presence of positive ions, the results in every case indicated two facts: (1) Only a part of the negative carriers were free electrons (probably twenty to forty percent) when the age of the ions was about 0.01 seconds, the newest that could be studied; (2) The total number of electrons remained approximately the same as the ions aged to 0.5 seconds or more, although a considerable portion of the negative carriers had disappeared by recombination. Thus negative ions and free electrons were probably both present in large quantities during the period of recombination, but there was no gradual attachment of free electrons taking place as would be expected if impurities were present. This can only lead to the conclusion that most of the attachment occurred within a few thousandths of a second after the formation of the ions, which would result if the effect were due to metastable excited molecules produced by the ionizing agent. This question will be considered further in the discussion of the results.

EXPERIMENTAL RESULTS

Values of the coefficient of recombination obtained in pure argon are shown in Fig. 1. The different curves correspond to commutator speeds varying from 16 to 1/2 revolutions per second. The initial concentration of the ions varied from about 2.5×10^6 ions per cm³ at 16 revolutions per second to 1.1×10^7 ions per cm³ at 1/2 revolution per second. The initial value of α at a time of 0.002 seconds is about 1.6×10^{-6} , and the value then drops off in a manner similar to that in air to about 0.55×10^{-6} at 0.75 seconds. A similar series of runs was next taken with the addition of 2 cm partial pressure of O₂ added to the A. This was sufficient to cause almost instant attachment of the

⁸ J. J. Thomson, *Conduction of Electricity Through Gases*, p. 102, III Edition, Cambridge 1928.

free electrons as indicated by the equality of the positive and negative readings. The results, however, (which are not shown in the diagrams)

Fig. 1. Coefficient of recombination for pure argon.

were exactly the same as for pure A within the limits of experimental error except at the very shortest time interval (0.002 seconds) where $\alpha = 1.7 \times 10^{-6}$

Fig. 2. Coefficient of recombination for argon with 15 cm partial pressure of O_2 .

instead of 1.6×10^{-6} . With the possibility that insufficient O_2 had been added, another series of runs was taken with 15 cm partial pressure of O_2 correspond-

Fig. 3. Comparison of results in pure argon and argon with 15 cm partial pressure of O_2 .

ing to the N_2-O_2 mixture in air. The results shown in Fig. 2 were again almost the same as in pure A except at the very shortest time when $\alpha = 2.0$

$\times 10^{-6}$. A comparison of the results obtained with pure A and A+15 cm O_2 are shown in Fig. 3. Average values of α for any particular age τ are plotted against τ . The A+ O_2 curve starts higher, crosses the pure A curve at about 0.005 seconds and continues on slightly lower for the remainder of the time.

Fig. 4. Coefficient of recombination for pure nitrogen.

Fig. 4 shows the results for pure N_2 which are not far different from the corresponding values for A. It was impossible to obtain accurate results at the fastest commutator speed (16 revolutions per second) owing to the lack of sufficient concentration of ions. Even at 8 revolutions per second (time of

Fig. 5. Results for air and hydrogen.

exposure to x-rays 0.0156 seconds) the concentration was only 0.91×10^6 ions per cm^3 which gave rather inaccurate values of α .

Fig. 5 gives the results for air and H_2 . Curves I to V were taken in air for varying commutator speeds under the conditions corresponding to those for A and N_2 ; i.e. with constant sector opening of 90° and as high initial concentration as possible. The initial concentration varied from 0.79×10^6 ions per cm^3 at 16 revolutions per second to 4.8×10^6 at $1/2$ revolution per

second. The value of α varies from 2.8×10^{-6} at $\tau = 0.008$ seconds to 0.55×10^{-6} at $\tau = 1.15$ seconds.

Curve VI, Fig. 5 gives the results for pure H_2 , showing a constant value of 0.32×10^{-6} for α between 0.15 and 1.15 seconds. Owing to the extreme difficulty of obtaining sufficient concentration of ions, no runs at commutator speeds faster than one revolution per second could be taken. Even at one revolution per second (time of exposure to x-rays 0.25 seconds) only 0.46×10^6 ions per cm^3 were obtained. At $1/2$ revolution per second the initial concentration was 0.90×10^6 ions per cm^3 . Argon in varying quantities was then added to the H_2 to obtain greater concentration of ions, but made no appreciable difference in the value of α up to 5 cm partial pressure. The results for 5 cm partial pressure of A with H_2 are shown in Curve VIII, Fig. 5. The values of α are only slightly higher than for pure H_2 , starting at about 0.50×10^{-6} at $\tau = 0.03$ seconds (commutator speed 4 revolutions per

Fig. 6. Comparison of results for pure gases.

second) and dropping to 0.40×10^{-6} at $\tau = 0.6$ seconds. Runs at commutator speeds of 1 and $1/2$ revolutions per second were next taken with 5 cm partial pressure of O_2 added to pure H_2 to obtain attachment of the free electrons. The results (Curve VII, Fig. 5) again show only a small change from those in pure H_2 , α dropping from 0.45×10^{-6} at 0.15 seconds to 0.35×10^{-6} at 1.15 seconds. A final series of runs was taken with 5 cm partial pressure of A and 5 cm of O_2 added to pure H_2 but gave results identical with those for 5 cm partial pressure of A (Curve VIII).

A comparison of the results for air, pure A, pure N_2 and pure H_2 are given in Fig. 6. As in Fig. 3 average values of α are plotted against τ the age of the ions. Except at the shorter time intervals the results show a marked similarity for air, N_2 and A despite the fact that free electrons in large quantities were undoubtedly present in the N_2 and A. The values of α for H_2 are strikingly lower than those for the other three gases.

DISCUSSION OF RESULTS

From the results in the preceding section four facts stand out clearly:

(1) The coefficient of recombination for pure A and N_2 where free electrons should be present is only slightly lower than for air except at very short time intervals (probably 0.05 seconds or less) when random distribution of the ions has not been attained.

(2) The coefficient of recombination in pure H_2 is much lower than in the other three gases having approximately a constant value of 0.32×10^{-6} .

(3) The addition of sufficient O_2 to cause instant attachment of free electrons in A, N_2 and H_2 increases the value of α at the very shortest time intervals.

(4) In A and N_2 the addition of O_2 apparently results in a slight lowering of the values of α after random distribution has been attained.

Regardless of the question of recombination between positive ions and free electrons, one definite conclusion may be drawn from these facts. When free electrons are present, the value of α is lower at the very short time intervals indicating that random distribution is attained more rapidly. This is of course to be expected since electrons would diffuse evenly throughout the volume much more quickly than negative ions and the so-called initial recombination would not occur to as great an extent.

Interpretation of results in A and N_2 . In regard to the question of recombination between positive ions and electrons the results are inconclusive. If theory and previous spectroscopic results are to be relied on, α should be so small (of the order of 10^{-10}) that no recombination could be observed in the present work where the concentration of ions is of the order of 10^6 per cm^3 . Either, then, the spectroscopic results (obtained at low pressures and generally in the presence of rather high fields) are not applicable here, or else recombination was occurring in the present case only between positive and negative ions. If α for positive ions and electrons is very low, and attachment were taking place gradually, the curves would be expected to start at a low value of α for short times, then increase as time goes on until all the free electrons had attached. However, no such low value of α at short time intervals was observed, the values actually increasing rapidly down to 0.002 seconds. Finally, then, one of two conclusions may be drawn: either recombination between positive ions and free electrons is as rapid as that between positive and negative ions, or else a large portion of the free electrons had attached in less than 0.001 seconds. The second view is strongly supported by the evidence obtained in the tests for the presence of free electrons which have already been described.

In view of the precautions taken to obtain pure gases, and the results of the tests for free electrons which indicated that a definite number of electrons were present at all times, it does not seem likely that many electrons had attached to molecules of impurity in 10^{-3} seconds. Nevertheless, such a conclusion might conceivably be in error. As already mentioned there is however another mechanism by means of which attachment might have

taken place in A and N_2 . The intense hard x-rays and fast β -particles produced by them undoubtedly excite a large number of molecules. If these excited molecules remain in metastable states for a considerable period of time (as in the case of active N_2) impacts between the excited molecules and free electrons could give a means of dissipating the electron energy and allow attachment to form negative ions. An effect of this kind has been observed by da Silva⁹ who found some attachment in N_2 and H_2 which had been ionized by α particles. A similar process might occur in A which also has metastable states. On the other hand Loeb¹⁰ and Cravath¹¹ observed no attachment in these gases where the electrons had been produced by ultra-violet light and hot filaments.

Interpretation of results in H_2 . Hydrogen presents a different problem from A and N_2 since metastable excited states do not exist. However, attachment may still take place to atoms or triatomic molecules as indicated by the results of da Silva. Observations in H_2 by Langevin,¹² Townsend¹³ and McClung¹⁴ indicated that the coefficient of recombination was slightly lower than in air (1.4×10^{-6} compared to 1.6×10^{-6}) while in the present work α was found to be 0.32×10^{-6} for H_2 compared to 1.4×10^{-6} for air. The present results may be assumed more reliable owing to the improvements in technique now possible. On the other hand, J. J. Thomson's theory of recombination as modified by Loeb and Marshall⁷ gives much higher values of α for H_2 than for air, even assuming the molecular weight of the ions to be 32 (since the negative ion is ordinarily a molecule of impurity such as O_2). In this case it turns out that α is 2.34×10^{-6} compared to 1.62×10^{-6} for air. If the molecular weight is taken as 2.016, α is 9.50×10^{-6} . Since in pure H_2 , α is observed experimentally to be much lower than in air, this might be taken as an indication of the presence of a preponderance of free electrons which would recombine slowly. However, the addition of sufficient O_2 to produce attachment of the electrons should then bring the value of α up at least as high as for air, probably higher. As shown in Fig. 5 very little change was observed. The theory, however, is based on the assumption that if both ions suffer a single impact when they are within a defined distance d of each other they will lose all the excess kinetic energy gained as a result of their mutual attractions since the last impact. This single impact is assumed a sufficient condition for recombination. Since the mass of the ions is probably large compared to that of the molecules, a single impact may not suffice to remove the excess energy and the ions may drift apart without recombining. In other words, several impacts are probably required to reduce the excess energy, which fact cannot be taken into consideration by the theory as it stands. In this way α could be less for H_2 than for air in agreement with the experimental results.

⁹ M. A. da Silva, *Ann. de Physique* **12**, 100 (1929).

¹⁰ L. B. Loeb, *Kinetic Theory of Gases*, p. 507, New York, 1927.

¹¹ A. M. Cravath, *Phys. Rev.* **33**, 605 (1929).

¹² P. Langevin, *Ann. de Chim. et de Phys.* **28**, 433 (1903).

¹³ J. S. Townsend, *Phil. Trans. Roy. Soc. A***193**, 157 (1900).

¹⁴ R. McClung, *Phil. Mag.* **3**, 383 (1902).

Thus, in view of the experimental facts it is probable that the recombination observed in this work was taking place between positive and negative ions rather than positive ions and free electrons. The negative ions may have been formed by attachment of electrons to impurities but the evidence points strongly to the supposition that the attachment was to metastable excited molecules in the case of A and N_2 , and to atoms or triatomic molecules in the case of H_2 .

Values of the recombination coefficient in various gases. As indicated earlier it is more difficult to set an "absolute value" of α in this work than in the previous work on air owing to unfavorable experimental conditions. However, if the value of α for air is taken as $1.4 \pm 0.1 \times 10^{-6}$ at the point where the sharp drop due to non-random distribution ends, and the more gradual drop due to aging begins, comparison of the curves in Fig. 6 indicates a value of $1.2 \pm 0.1 \times 10^{-6}$ for A and N_2 . The value for H_2 may be more definitely set as $0.32 \pm 0.05 \times 10^{-6}$ since in this case there is no appreciable change with time.

A list of values for the coefficient of recombination determined by the above criterion for all the gases studied may then be given as follows:

<i>Gas</i>	<i>Coefficient of Recombination</i>
Air	$1.4 \pm 0.1 \times 10^{-6}$
O_2	$1.5 \pm 0.1 \times 10^{-6}$
N_2	$1.2 \pm 0.1 \times 10^{-6}$
A	$1.2 \pm 0.1 \times 10^{-6}$
H_2	$0.32 \pm 0.05 \times 10^{-6}$

In conclusion the writer wishes to express his sincere thanks to Mr. N. E. Bradbury for assisting in taking the readings and to Professor Loeb for his inspiring guidance throughout the course of these experiments.

THE MOBILITIES OF IONS IN DRY AND MOIST AIR

BY JOHN ZELENY

SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received May 26, 1930)

ABSTRACT

With the method recently described the distribution of mobilities of aged ions in dry air has been determined and the values for moist air remeasured because of a neglected correction in the previous results. In air dried by passage through metal tubes and filters immersed in liquid air the negative ions were found to consist of two main groups of which the less numerous group comprises about one third of the total number of ions and has a peak mobility only about 60 percent of that of the main group. The number of ions in the lesser group was relatively smaller in air dried by calcium chloride alone and their presence in still smaller numbers in air having a water content of 2 mg per liter accounts for the dissymmetry in the distribution curves of negative ions in moist air reported in the previous paper. The distribution curves for positive ions in dry air also show some indications of two groups of ions only here the ions of the less numerous group, which does not appear in moist air, have a peak mobility about 40 percent higher than those of the main group. The absolute values of the peak mobilities found for the main group of negative ions in the driest air used for a pressure of 76 cm and a temperature of 20°C was 2.45 cm/sec. This diminished to 2.37 cm/sec for air dried by calcium chloride, and to 2.08 cm/sec for air containing 2 mg of water per liter. Under the same conditions the mobilities of the positive ions increased in succession from 1.05 cm/sec to 1.10 cm/sec to 1.36 cm/sec. These large opposite changes produced by a small fraction of one percent of water molecules can only be explained on the supposition that aged ions in air consist of molecular clusters whose structure is affected by the presence of water molecules. The second group of negative ions cannot consist of ions having multiple electronic charges, because the mobility of these ions is smaller than that of the main ion group. It cannot arise from the presence of impurities condensable at liquid air temperatures. Since electrons do not readily become attached to nitrogen molecules, the central molecule of each of these ions is probably an oxygen molecule and the two cluster groups may arise either from a difference caused by a different point of attachment of the electron to the central molecule or from the nature of the molecule that first becomes attached to this central molecule in the process of cluster formation.

IN a recent paper¹ I reported some results on the mobilities of well-aged ions in moist air which showed that the ions of each sign are not all alike. No distinct groups were resolved but the mobilities in each case were found to be spread continuously over a range of values. Within this range, the positive ions as regards numbers present were distributed quite symmetrically about a most numerous kind, while the negative ions had mobility values extending much farther in the direction of lower mobilities than in the direction of higher mobilities.

¹ J. Zeleny, *Phys. Rev.* **34**, 310 (1929).

The method employed in the mobility measurements has some distinct advantages over other methods which have been used, and the work with it has now been extended to dry air.

The new results disclose for negative ions in very dry air a second group of ions comprising about one-third of the total number and having a mobility only about six-tenths of that of the ions in the main group. Indications of this new group in smaller numbers are well marked in air dried by passage through calcium chloride alone, and the presence of these ions in still smaller numbers also accounts for the lack of symmetry mentioned above in the distribution curves for negative ions in moist air.

Some indication too was found that among positive ions in very dry air a second group of higher mobility than that of the main group is also present.

The peak mobility of the main group of positive ions was found to decrease quite markedly when the air was dried, while that of the main group of negative ions increases with removal of moisture.

The method used consists in blowing a nonturbulent stream of air between two concentric cylinders, admitting ionized air into this stream through small openings in the outer cylinder, and measuring the distance the ions are carried down stream while they are crossing the space between the two cylinders under the action of an applied field.

The average velocity of the main air stream with which the velocity of the ions was compared was maintained throughout these measurements at approximately 8 cm/sec. This low velocity is well within the limits of nonturbulent motion in the apparatus used. The potentials used on the outer cylinder were such as allowed the ions in crossing to be carried down stream only far enough to permit an accurate determination of the distance, in order to keep the correction for ion diffusion as small as possible.

Reference should be made to the previous paper¹ for details regarding the apparatus and for the procedure used in reducing the observations, as well as for references to the work of other observers.

A few modifications were made in the apparatus. The connecting tubes were all made of metal or glass. The openings in the outer cylinder through which the ionized air is admitted into the main gas stream were enlarged and now consist of 20 slots along a circumference, each slot being 1 mm wide and 9 mm long. The total area of these openings is now such that with a stream of ionized air delivering 9.8 cc per sec. as was used throughout these measurements the correction which has to be applied to mobility determinations to allow for the penetration of this ion stream into the main air current is on the average less than one-half of one percent.

The movement of the inner cylinder with its insulated ion collector ring is now effected by a threaded micrometer head working on a rod extending from the system to be moved to the outside of the apparatus. This improvement makes possible more rapid and more accurate settings of the ion collector ring.

The radioactive material used for producing ions in the auxiliary chamber during these measurements consisted of a deposit of polonium on a nickel

strip which was wound around the outside of the outer cylinder a short distance up stream from the openings through which the ions entered the main gas stream. The polonium coating was sealed gas tight by a covering of thin condenser paper.

The age of the ions as they entered the main gas stream was on the average about 3 sec. although some of the ions were only about 1 sec. old.

The air for the main gas stream was supplied by the pressure system of the laboratory. To dry the air, it was passed in succession through a large filter, through a 16 cm wide bottle containing granulated calcium chloride, through a second filter, through a long copper coil of small diameter immersed in liquid air, and finally through a second copper coil immersed in a water bath maintained at room temperature. The air for the auxiliary ion bearing stream was passed through a similar, separate drying system. In some of the last measurements, additional filters immersed in liquid air were added to the drying system. These contained first a section filled with coarse metal filings to ensure a closer contact between the cold surfaces and the air, and then closely packed glass wool to remove any crystals of ice which might be blown along by the stream and later be changed to vapor.²

Measurements of the mobilities of both positive and negative ions were made not only in air dried as has just been described, but also in air dried much less thoroughly by calcium chloride alone, and in undried air of low but determined humidity. These last measurements are included because the absolute values given in my last paper for the mobilities in moist air are somewhat low owing to the fact that the air pressure at the gauge used for measuring the stream velocity was unwittingly allowed to exceed the limit within which no correction for this pressure had to be made. A mercury manometer, previously removed to avoid the presence of mercury vapor, was now kept at this gauge and the gauge was recalibrated for the same gas pressures as were used in the measurements.

AIR DRIED BY AID OF LIQUID AIR

Curve *A* of Fig. 1 gives an example of the way in which negative ions were found distributed along the inner cylinder, when the air used was dried as described above by passage through calcium chloride and through a long helical tube immersed in liquid air. The abscissas give the down stream distances from the place of entry of the ions into the air stream and the ordinates give the corresponding ion numbers. The difference of potential between the two cylinders was 12 volts. The curve of distribution is a compound one, and by drawing the two branches *c* and *d*, the sum of whose ordinates for any abscissa is equal to the corresponding ordinate of the experimental curve, the compound curve may be resolved into two simple curves having peaks at *a* and *b*. The observed distribution thus shows the presence of two distinct groups of ions, of which those of higher mobility are about twice as numerous as those of lower mobility. Some of the other

² H. A. Erikson, Phys. Rev. 34, 642 (1929).

similar observations show a small number of ions carried even farther down stream than is here apparent, indicating ions of still lower mobility. The mobility corresponding to the peak of the less numerous group of ions was found to be on the average 1.45 cm/sec. which is about six-tenths of the value for the main group.

Curve *B* of Fig. 1 is an example of corresponding results obtained for positive ions. The difference of potential between the cylinders was 15 volts. The main air stream and the ion bearing stream as well were passed in this case through calcium chloride and tubes immersed in liquid air and subsequently through a cylindrical metal box, also immersed in liquid air, which contained a layer of fine metal turnings and closely packed glass wool.

Fig. 1. Distribution of ions in dry air. Ordinates represent number of ions corresponding to down stream distances given as abscissas. Curve *A* is for negative ions in air dried by passage through tubes immersed in liquid air. Curve *B* is for positive ions where a filter immersed in liquid air was added to the drying system.

Curve *B* shows an entirely different distribution of ions than that found for negative ions. The dotted ordinate drawn through the peak of the curve shows that now the number of ions on the upstream side of the peak is greater than on the downstream side. There is a bulge in the curve near the abscissa distance 2.2 cm which appears also in all of the other similar observations, indicating the possible presence of an unresolved group of ions having a peak mobility of about 1.5 cm/sec., the mobility of the ions at the main distribution peak being here only 1.06 cm/sec.

A summary of the mobilities found for the peak of the distribution curves of the main group of ions in air dried by use of liquid air is given in Table I. The uncorrected potential of the outer cylinder relative to the inner one is indicated in each case. These results, as well as all others to be given, have been reduced to a temperature of 20°C and a pressure of 76 cm of mercury.

The unusually large difference between the positive and negative mobilities is to be noted. This difference is much larger than can be accounted for according to prevailing theories by a difference of mass alone. Linear dimen-

TABLE I. *Peak mobilities of predominant group of ions in very dry air.*

(a) Air dried by CaCl ₂ and tubes in liquid air.			
+12 volts	1.10 cm/sec.	-12 volts	2.40 cm/sec.

+15 "	1.04 "	Negative ions	2.45 cm/sec.
Positive ions	1.05 cm/sec.		

sions of the ions must be invoked as a prominent factor in determining such variation in mobility.

The presence of the extra filters immersed in liquid air appears to have resulted in a more complete drying of the air, since the positive ion mobilities in (b) the lower portion of the table are on the average a little smaller than in (a) the upper portion, and those of the negative ions are a little larger. The amount of water remaining in the air after the above treatment must be very small. The computed amount at -194°C given in the International Critical Tables is 1.6×10^{-23} mg per liter; naturally such a low value cannot be approximated in the apparatus used.

The total spread of ions when they arrive at the inner cylinder as shown by the curves of Fig. 1 does not represent altogether ions of different mobilities. A part of the spread arises from diffusion and mutual repulsion of the ions during their passage between the two cylinders. A method of correcting for these effects is fully described in my previous paper,¹ and when applied to the results for positive ions shows that ions are present ranging in mobility from 0.83 cm/sec. to 1.58 cm/sec., the two possible groups present being treated as one. Owing to the partial overlapping of the two groups of negative ions, the spread of mobilities in the main group having the faster ions can only be obtained for the upstream side of the peak. The fastest ions here were found to have a mobility 11 percent greater than the peak mobility. In the group of lower mobility the estimated spread on either side of the peak mobility is between two and three times the above value.

The high value of the peak mobility of negative ions here given is in agreement with that obtained by Schilling³ likewise in very dry air but for ions of lesser age. The mobility of the positive ions here found for very dry air is lower than values hitherto reported. It must be remembered that this value corresponds to the peak of a distribution curve which shows strong indications of a less numerous group of higher mobility. Schilling makes note of the fact that the curves he obtained with positive ions, using the alter-

³ H. Schilling, *Ann. d. Physik* **83**, 23 (1927).

nating field method, were of a form to be expected from a mixture of different ions.

AIR DRIED BY GRANULATED CALCIUM CHLORIDE

A number of measurements were made with air dried by passage through granulated anhydrous calcium chloride only, this being known as a rather poor drying agent and leaving in air water to an amount of about 0.2 mg per liter.⁴

Examples of the ion distribution curves obtained under these conditions are given in Fig. 2, where curve *A* represents negative ions and curve *B* positive ions, the voltage used being 15 volts in each case.

Fig. 2. Distribution of ions in air dried by calcium chloride. Curve *A*=negative ions. Curve *B*=positive ions.

The curve for the negative ions, in addition to the main group represented by the high peak, also shows the existence of ions of a smaller mobility but these are less numerous than was found to be the case (curve *A*, Fig. 1) with air more completely freed of water molecules.

The curve for the positive ions does not show the bulge seen on curve *B* of Fig. 1, although the dotted ordinate drawn through the middle of the peak helps to show the presence here also of a larger number of ions of mobility greater than the most numerous kind than there are of ions with a smaller mobility.

⁴ A. T. McPherson, Jour. Am. Chem. Soc. 39, 1317 (1917).

Table II gives a summary of the results for the peak mobilities of ions in air of this degree of dryness.

The values for the positive ions are here a little larger and those for the negative ions somewhat smaller than those given in Table I.

The positive ion group was found to extend between the same limits as given above for positive ions in air dried by aid of liquid air. The main negative ion group extends from a peak mobility of 2.37 cm/sec. up to 2.54 cm/sec. The presence of a group or groups of negative ions of lower mobility here also prevents the getting of an estimate of the value of the lower limit of the mobilities in this main group.

AIR WITH AVERAGE WATER CONTENT OF 2 MG/LITER

Fig. 3 gives examples of the distributions found for ions in filtered air drawn directly from the pressure system of the laboratory, and containing on the average 2 mg of water per liter. The air for the auxiliary stream in

Fig. 3. Distribution of ions in air having a water content of 2 mg per liter. Curve *A* = negative ions. Curve *B* = positive ions.

which the ions were produced was supplied by a gasometer containing water and carried on the average 13.6 mg of water per liter. As this air did not mix with the main air stream, it is probable that the mobilities obtained are the same as would have been obtained had the ion bearing stream contained the same amount of water as was present in the main stream.

The positive ion distribution curve *B* shows the ions to be almost equally distributed on the two sides of the peak value. The negative ion curve *A* is again far from symmetrical but the group of ions of lower mobility, clearly indicated in Figs. 1 and 2, here shows only as an extended foot of the curve for the main ion group. It appears therefore that this low mobility group of ions forms a smaller and smaller portion of the whole number as the amount of water present in the air is increased. Its presence accounts for the lack of symmetry, reported in the previous paper, in the distribution curves for negative ions in moist air. The positive ions are spread over a somewhat smaller range of values here than is the case in dry air.

A summary of the results for moist air is given in Table III.

TABLE III. *Peak mobilities in moist air.*

+12 "	1.98 "	1.35 "			
+15 "	1.33 "	1.37 "		Negative ions	2.08 cm/sec.
+15 "	2.89 "	1.38 "			
Positive ions		1.36 cm/sec.			

The water content of the air used in the main gas stream is given in milligrams per liter in the second and fifth columns. The water molecules in the stream formed only about one quarter of one percent of the total number and yet their effect on the mobilities of the ions is seen, by comparison with the values of Table I, to be quite marked, the positive ion mobilities being increased by about 30 percent and the negative ions decreased by about 18 percent relative to those obtained in the driest air used. It is not possible to account for these large opposite effects on the two ions by an increase in the resistance to their motion due to the presence of the water molecules. It is necessary therefore to postulate that aged ions consist of molecular clusters and that the water molecules produce a change in their structure, such that the size of the positive ion cluster is diminished and that of the negative ion increased.

The increase in the mobility of positive ions produced by the presence of water molecules as given above confirms my earlier results and is in agreement with the results of Blanc⁵ and Laporte⁶ for ions of lesser age. Several other observers have obtained an opposite effect of moisture upon the mobility of positive ions, but it must be noted that in general the ions used have been much less aged than was the case in the experiments being reported. Valta⁷ using very young positive ions found their mobilities to decrease both with age and with water content of the air and has obtained in very dry air values as high as 6.8 cm/sec. Nolan and Nevin⁸ found remarkable fluctuations in the values of the mobilities of ions of both signs as the water content of the air was increased. It is difficult to reconcile all of these different experimental results on the effect of moisture on ionic mobilities in air.

The results given above clearly show the presence of two groups of aged negative ions in very dry air. The group of lower mobility has about one-half as many ions as the one of higher mobility. The relative number of these slower ions is considerably smaller in air dried by calcium chloride alone, and is still less in air having a water content of 2 mg per liter.

⁷ Z. F. Valta, Journal of Geophysics and Meteorology (Russian) 6, 197 (1929).

⁸ J. J. Nolan and T. E. Nevin, Proc. Roy. Soc. A127, 155 (1930).

It is of theoretical interest that among aged ions it is possible under any circumstances for two distinct groups of small ions to coexist. It is improbable that the new group consists of ions with multiple charges which tend to become reduced to unit charges in the presence of water molecules, since all of the evidence points either to an increase of mobility with increase of charge or to an independence of mobility of the ionic charge. The presence of some unusual impurity might be thought to give rise to the new ion group. If such an impurity consisted of vapors coming from the compression pump or elsewhere, we should expect its effect to be least pronounced or absent when the air was passed through tubes immersed in liquid air where such vapors would be condensed, whereas the opposite was found to be the case.

It is probable therefore that the two negative ion groups under discussion consist of clusters of molecules the center of each of which is a molecule of one of the chief constituents of the atmosphere, to which an electron has become attached. Since electrons do not attach themselves readily to nitrogen molecules the central molecules are probably oxygen molecules. The evidence available is not sufficient to account satisfactorily for the two negative ion groups, but we may suppose that the difference in cluster size arises either from a difference in place of attachment of the electron to the molecule or from a difference in the kind of molecules that by chance first become joined to the central charged molecules during the formation of the clusters.

I am indebted to Mr. R. S. Baldwin and to Mr. C. D. Bock for aid with the measurements.

EXCITATION PROCESSES IN THE HOLLOW CATHODE DISCHARGE

BY RALPH A. SAWYER

UNIVERSITY OF MICHIGAN, ANN ARBOR

(Received May 19, 1930)

ABSTRACT

The low potential gradients in the negative glow in a hollow cathode discharge in a rare gas make it a favorable source for the excitation of metallic spark spectra. The metal studied forms the cathode, and is brought into the discharge by cathode sputtering or evaporation. The excitation is limited by collisions of the second kind between gas and metal atoms and ions. The spectroscopic data of all the available cases have been examined to see what determines the processes occurring. In general only those processes occur in which the metal can be excited to some term in the spark spectrum with gain or loss of only a small amount of kinetic energy to balance the reaction equation. High melting point metals or those which sputter poorly cathodically enter the discharge in helium in the normal state or in a low metastable state of the atom. With low boiling points metals appreciable numbers of metal ions enter the reactions. In intermediate cases or in argon or neon, it is not always possible to predict if metal ions will enter the reaction or not. The conditions which determine the results are discussed.

THE excitation of metallic spectra by the discharge in a hollow cathode tube in a rare gas atmosphere has been discussed by Paschen,¹ Frerichs² and Takahashi.³ While there is general agreement that the excitation is mainly limited by collisions of the second kind between rare gas atoms or ions and metallic atoms or ions there has not been agreement as to the exact nature of the collisions. Paschen and Frerichs have attributed the fundamental process to collisions between metallic ions and excited metastable rare gas atoms. Takahashi on the other hand considers only normal or metastable metallic atoms which receive energy from metastable atoms or ions of the rare gases. On the basis of somewhat more experimental material than was available at the time the discussions mentioned above were written, it is now possible as will be shown in this paper to explain the processes involved somewhat more fully and to show that under suitable conditions any of the excitations proposed by the author's mentioned may occur.

The conditions on the hollow cathode are rather different from those in other discharges. With such a cathode, often though not necessarily inside a cylindrical anode, and an applied D.C. potential of 300 or 400 volts, at a suitable pressure which depends on the cathode dimensions, the discharge is almost wholly inside the cathode. The discharge then consists of a negative dark space close to the inner wall of the cathode and a very bright negative

¹ Paschen, Sitzungsber. d. Preuss. Akad. d. Wiss. p. 207 (1927).

² Frerichs, Ann. d. Physik 85, 362 (1928).

³ Takahashi, Ann. d. Physik 3, 49 (1928).

glow filling the cathode. The positive column practically disappears. This discharge was first used as a spectroscopic source by Paschen.⁴ It was explained by Günther-Schulze⁵ who showed that when the pressure was decreased in such a tube until the mean free path of electrons leaving the inner wall of the cathode was sufficient to bring them into the positive space charge of the opposite side of the inner wall they would there reduce this charge causing an increased current and a lower cathode fall of potential inside and so setting up a condition permitting a very much greater current density from the inner wall of the cathode than from the outer. The discharge then takes place chiefly inside the cathode. The pressure at which this effect will occur depends on the diameter of the cathode and the nature of the gas. It is a pressure such that the normal cathode dark space is about equal to the inner radius of the hollow cathode. The discharge however is formed inside the cathode with an abnormal dark space thickness much less than normal. This space inside the negative glow of the hollow cathode is nearly field free and ions may exist there in considerable concentrations and radiate freely even from states of high quantum number. The negative glow in the hollow cathode is very brilliant and this light source is one of the best for exciting the first spark spectra of the metals.

The metallic atoms which enter the discharge are removed from the cathode wall by ionic bombardment and evaporation. In the analogous case of cathode sputtering Von Hippel⁶ found with argon at 0.1 mm pressure in spectrograms of the light just at the cathode surfaces that the only spectral lines of the cathode material which appeared were the resonance lines of the atom. From this he concluded that the material is given off in an atomic state and arrives in the negative glow by a diffusion process. His theory is that intense local heating of the cathode by ion bombardment causes minute hot spots from which the cathode metal is evaporated. If the resonance lines of the cathode metal appear near the cathode, the cathode metal must enter the discharge as excited atoms as well as normal atoms. Ions knocked off the cathode could not normally penetrate the high cathode fall of potential in the hollow cathode (100–300 volts according to measurements of Schüler).⁷ We may expect in general in the negative glow of the hollow cathode reactions with metallic atoms both neutral and excited (in metastable states) although, as will be pointed out later, under certain conditions significant numbers of metal ions may enter the reactions. These metallic particles entering the negative glow suffer collisions with rare gas particles, or with electrons whose velocity is limited by collisions with rare gas atoms. The spectrum of the negative glow shows the spectrum of the ionized exciting gas very strongly. In fact with a grating not particularly good below $\lambda 300$ Sawyer and Lang⁸ observed in the discharge in helium as many as four

members of He II series 1^2S-m^2P beginning at $\lambda 304$ and Paschen⁹ under suitable pressure and current conditions has observed in the hollow cathode in helium Stark effect in the higher members of the helium series due to the electric fields of the great concentration of helium ions. It is then to be expected that excited atoms in the metastable state and ions in the normal state will be the predominating energy states in which the rare gas will be found and that the transfer of these energies to the metallic atoms will fix the limiting conditions of excitation for the spectrum of the metal.

To check these considerations there are available data for the hollow cathode excitation of aluminum, copper, magnesium and zinc in helium, argon and neon; cadmium in helium and argon; and gallium, mercury and thallium in helium.¹⁰ Not all of these data are well adapted for the study of the question in hand. In some cases the investigation did not cover a sufficiently wide spectral region to permit a certain determination of the kind of excitation attained in the discharge. In others the limit attained is low and so the terms too few and too far apart to fix the limit sharply. For the sake of completeness it has, however, all been assembled.

TABLE I. *Important energy levels of metallic spectra.*¹¹

Normal State of Atom				Metastable State of Atom			Normal State of Ion		
Config.				Config.			Config.

For each of the metals mentioned above Table I gives the electron configuration of the normal state of the ion and of the first state and of the lowest metastable state of the atom. In aluminum this metastable state is the lowest $^2P_{1/2}$ of the normal configuration and is too near $^2P_{3/2}$ to be differentiated in the data at hand. Table I also gives for each configuration the energy of removing the outermost electron from this configuration—that is to excite the metal to the lowest or normal state of its next ion. For con-

¹¹ The data in table II are taken from Paschen-Götze "Seriengesetze der Linienspektren" or from the references in footnote 10.

venience in spectroscopic discussion this value is given in ν -units. It may of course be converted to equivalent volts by multiplying by 1.2345×10^{-4} . For the three rare gases the atomic energies available are, also in ν -units

	Energy of ionization	Energy of metastable state
Helium	198308	159830 (2^3S) or 166251 (2^1S)
Neon	173930	134819
Argon	127104	94546

From the energy available from the rare gas atoms together with the data of Table II there may be calculated the highest spectroscopic state of the metal ion which should be excited by any of the probable collisions of the second kind with a rare gas. Thus for example $\text{Zn}'(d^{10}s p^3 P_0) + \text{He}'(2^3S) \rightarrow \text{Zn}^+(?) + \text{He}(1^1S) + e$ we have:

energy to ionize metastable zinc	43450
energy to doubly ionize first zinc ion	144890
	<hr/>
	188340
energy of He (2^3S)	159830
	<hr/>
	28510

Thus, this reaction fails by 28510 ν -units to achieve second ionization, or a Zn II term of absolute value (measured from ionization) 28510 would just be excited. The results of such computations are listed in Table II, where in the column heads M stands for the metal concerned and G for the gas. Reactions with $\text{He}'(2^1S)$ are not listed. The results of a reaction with $\text{He}'(2^1S)$ may be obtained by subtracting 6421 from the term obtained by a reaction with $\text{He}'(2^3S)$.

The processes in italics are those which account for observed features of the spectra.

The experimental results of interest in this discussion are tabulated in the two right hand columns of Table II. In each case where it is certainly determined there is given the limit, that is, the highest spectral term of the metal ion excited in the rare gas atmosphere. There is also given any observed maximum of excitation—any terms which appear to be excited more strongly than immediately lower terms—indicating resonance phenomena in the exciting process.

A comparison of the calculated and observed excitation in Table II shows that many of the observed features of the spectra may be explained on the basis of various of the exciting processes. The cases will be discussed in order of their simplicity.

Aluminum, gallium and thallium are all high boiling point metals. Aluminum sputters cathodically less than any other metal tried. Consequently the concentration of these metals in the hollow cathode discharge in helium is very low; they react only as normal atoms or possibly in the case of gallium and thallium as atoms in the very low metastable $^2P_{1/2}$ state. The limit is clearly set in the case of excitation in helium by $M+G^+$ or $M'+G^+$. There are no resonance maxima in these cases because, although the process $M+G'$ must contribute to the excitation, the limit of this excitation falls where the spectral terms are not numerous enough nor close enough together to make such a maximum apparent.

In the case of aluminum in argon and neon a new effect enters. The limit here is obviously set by M^++G' . That is, metal ions are entering this discharge although the concentration of metal in these cases is still so small that metal ions are not to an appreciable extent current carriers, as does occur in cases to be mentioned later. The greater number of metal ions is here due probably to the heavier bombardment of the cathode by the heavier gas particles. A similar effect appears in the vacuum spark where increased voltage on the spark giving heavier bombardment of the electrodes brings higher ionized atoms into the spark.

The limit of excitation for magnesium in helium and neon appears to be set respectively by the reactions $M'+G'$ and $M+G^+$, although these cases have perhaps not been investigated over a sufficiently wide spectral range for absolute certainty as to the limit.² In the neon the excitation goes somewhat (1/3 volt) above $M+G^+$ and a maximum corresponding to resonance with this process in the series 3^2D-m^2F is clearly seen. The energy for overshooting of the limit, $M+G^+$, probably comes from kinetic energy of the atoms. The process, M^++G' , which sets the limit for Al+Ne probably does not occur here. It would call for excitation 13235 cm^{-1} beyond double ionization and as negative terms in Mg II are not possible and as there are no terms in Mg III as low as this, this process would involve freeing an electron with this surplus energy—a process which seems improbable. It will be seen that for magnesium and argon the limits of the five different processes are well separated and all positive. However, this case is not so favorable for observation as it seems for most of the limits are too low in the Mg II spectrum to allow maxima of excitation to be observed. It will

be noted from Table II that Frerichs observed excitation 10256 cm^{-1} above the highest limit. It is not clear how this can occur. A similar anomaly occurs with zinc in argon but in no other observed cases. It may be that here the reaction is with some high excited state of the metal atom but what state could occur with sufficient probability is not obvious.

Copper should offer an excellent opportunity to study excitation conditions in the rare gases since all the processes give rise to positive terms in Cu II. The copper spectrum is, however, unfortunately not completely analyzed and the combinations of the highest known terms lie largely in the extreme ultra violet. The highest term found by Kruger in helium, however, seems clearly to arise from $M' + G^+$. The process $M + G^+$ is responsible for a maximum of intensity found by Kruger for terms from $27\text{--}30000\text{ cm}^{-1}$. Frerichs' work in neon did not lead to determination of any limit, but in argon the limit is set by $M^+ + G'$ again, as with aluminum in neon and argon.¹²

Zinc, cadmium and mercury represent a different type of excitation condition. These metals have low boiling points and relatively high vapor pressure at the cathode temperature in the hollow cathode discharge. The ions of these metals enter the discharge in such concentrations as to carry a considerable part of the current. In fact in mercury the discharge may be operated without any rare gas using a carbon cathode and allowing the heat of the discharge to vaporize the mercury. Under such conditions we may expect that in all cases where the process $M^+ + G'$ gives rise to actual terms that this reaction will set the limit to the excitation. This is indeed the case as will be seen by reference to Table II. In all these metals negative terms in the spectrum of the ion are possible and have been found so that the excitation has been traced to the highest limit permissible in helium. In zinc and cadmium the limit given in Table II is in fact exceeded by $3000\text{ }\nu$ -units. This is possibly due to reaction with the higher metastable helium term (2^1S) which as pointed out previously would give excitation 6000 cm^{-1} higher than 2^3S which is given in the table. In the spectra of all these three metals some unclassified lines remain and more negative terms may be found to reach the limit $M^+ + \text{He}'$ (2^1S). In helium with each of these metals there is also found maxima of excitation explainable as resulting from $M + G^+$ which appears in these cases to be more probable than $M' + G'$ no doubt because M' is so high in these metals that it is less likely to be excited strongly than in the case of copper or magnesium. The metals have not been studied in neon with the exception of zinc where, however, the spectral range covered by Frerichs was not sufficient to permit conclusions to be drawn. In argon, however, the limit is clearly set by $M^+ + G'$ with cadmium while with zinc, as mentioned above, even this limit which is the highest set by the simpler reactions, is exceeded by 25000 cm^{-1} . This, as in the case of $\text{Mg} + \text{A}$, does not appear susceptible to obvious explanation.

¹² Frerichs terms have been corrected to the true lowest term in Cu II not known at the time of his work.

In conclusion it may be said that the excitation of metallic spectra in the hollow cathode discharge in rare gases does not give results which are entirely predictable. In general with metals which do not sputter too freely nor have too high vapor pressures at the cathode temperatures, as Mg and Al, the reaction $M+G^+$ together with $M'+G'$ and $M'+G'$, if M' is low, will occur, and the highest of these will set the limit to the excitation if this does not call for non-existent negative terms. With such metals in neon or argon M^++G' will in general occur due to the greater kinetic energy with which they bombard the cathode. With metals of high vapor pressure, as zinc, cadmium or mercury, M^++G' will always set the limit if the terms called for are possible—i.e. not impossible negative terms.

While the limit of excitation will be set by whichever of the possible processes, as described above, possesses the greatest energy which the metal atom or ion can absorb, the processes leading to lower excitations will manifest themselves by maxima of excitation of the terms with which they are nearly in resonance, providing these excitation levels fall where the M^+ terms are close enough together for such maxima to be distinguishable.

For metals intermediate between the types above discussed it does not appear on the basis of present information possible to predict the excitation conditions. Whether or not metal ions will play a conspicuous part in the excitation will apparently depend too much on current density, cathode temperature and gas pressure in particular cases. Altering any of these may influence widely the character of the discharge. It would seem that by placing the metal in a carbon cathode whose temperature could be controlled by the discharge current density or by external heating, it should be possible to pass at will, by varying the vapor pressure of the metal and the gas pressure from the case of low vapor pressure with $M+G^+$ as limit to that of high vapor pressure with M^++G' as limit. A complete theory of the discharge under all conditions and for all gases and metals is not yet possible.

ANALYTIC ATOMIC WAVE FUNCTIONS

BY CLARENCE ZENER
MANCHESTER, ENGLAND

(Received May 26, 1930)

ABSTRACT

The wave functions for the atoms Be, B, C, N, O, F, Ne, are written as simple analytic expressions with several parameters. The best values of these parameters are then determined by the variation method. In the final wave functions the effective quantum number is very nearly two, the radial node is so small as to have little effect upon the charge distribution, the coefficient in the exponential is related to an empirical "mean effective charge."

INTRODUCTION AND RESULTS

SEVERAL methods may be used to obtain approximate solutions of the wave equation for a many electron atom. Any one method cannot claim superiority in every respect. One naturally wants that type of solution which can be used to the best advantage. If he wants information derivable from a graphical $\psi\bar{\psi}$ distribution, then the Hartree¹ functions will be the best. In fact, the graphical method of integration, modified in the manner suggested by Slater² and Fock³ to include resonance, will give the best approximation in which the total ψ is built from functions of only one electron, and in which magnetic forces are neglected.

If all questions could be answered by graphical functions without an undue amount of labor, we would not be justified in finding a less correct analytical ψ . But the integrals representing the mutual potential energy of two atoms are of a type which can be readily evaluated only when the wave functions are given by analytic expressions. Moreover, these integrals become increasingly laborious as the complexity of the atomic functions increases. Hence it is desirable to know the best possible functions which can be represented by simple analytic expressions.

Such atomic functions may be obtained starting from the hydrogenic solutions, exact when the interaction between the electrons is neglected, then partially taking care of this interaction by putting parameters into the function wherever flexibility may be obtained without increased complexity. This method has been used to obtain an approximate eigenfunction for Li by Guillemin and Zener.⁴ In this paper the same method is applied to the normal states of the remaining elements in the first row of the periodic table.

³ V. Fock, Zeits. f. Physik **61**, 126, (1930).

⁴ V. Guillemin Jr. and C. Zener, Zeits. f. Physik **61**, 199, (1930).

Slater⁵ has shown how to write the wave function of a many electron system without the use of the group theory. Since the normal states here considered are states of highest multiplicity, the complete ψ may be written

$$\psi = \frac{1}{n!^{1/2}} \sum_P (-1)^{\sigma_P} P u(1/x_1) u(1/x_2) u(s/x_3) \cdots \\ \delta(-\frac{1}{2}/m_{s_1}) \delta(\frac{1}{2}/m_{s_2}) \delta(-\frac{1}{2}/m_{s_3}) \cdots$$

n is the number of electrons; P is an operator which permutes the electron numbers; σ_P is the order of the permutation P ; $u(r/x_i)$ is a space coordinate function of the i^{th} electron in the r^{th} quantum state; $\delta(m_s/m_{s_i})$ is the spin function of the i^{th} electron in a state with spin component m_s . The summation is over all permutations.

We shall denote the states (100), (200), (21-1), (210), (211) by 1, s , a , b , c respectively. The normalised u 's which have been generalised from their hydrogenic form are

$$\begin{aligned} u(1/x) &= g_1 e^{-\gamma r} \\ u(s/x) &= g_2 r^{n^*-1} (1 - \alpha r^{-1}) e^{-\delta r} \\ u(b/x) &= g_3 \cos \theta r^{n^*-1} e^{-\delta r} \\ \left(\frac{a}{c} / x \right) &= g_4 \sin \theta e^{\pm i\phi} r^{n^*-1} e^{-\delta r} \end{aligned}$$

where r is written in units of a_H . In every atom the four parameters n^* , α , γ , δ are to be determined by finding that set which makes

$$J = \frac{\sum_{m_{s_i}} \int \psi H \bar{\psi} d\tau}{\sum_{m_{s_i}} \int \psi \bar{\psi} d\tau} \quad (1)$$

a minimum. H is the Hamiltonian operator without magnetic interactions. It is found that γ changes little from its value

$$\gamma = (N - 5/16)$$

in helium-like ions⁶ (N equals atomic number). In Ne, where interpenetration is the largest, the change is from 9.69 to 9.64. This variation in γ does not affect the minimal value of δ in the significant figures used. It is of interest to note that the resonance of the two $2s$ electrons counterbalances their interpenetration to give a net negative shielding of the K shell.

The minimal values of the remaining parameters are in Table I.

The small effect of α upon the charge distribution is shown in Fig. 1 for Be. Here the quantity

⁵ J. C. Slater, Phys. Rev. **34**, 1293 (1929).

n^* has been varied only in Li and Be. Since in both atoms it has its hydrogenic value, it is to be expected to retain this value in the remaining atoms.

Fig 1.

A is electron density $\times r^2$ with $\alpha=0$, crosses indicate values when $\alpha=0.15$.

B is negative of resonance charge density $\times r^2$

In the elements Be to Ne δ is 0.05–0.06 less than the “mean effective charge” defined by

$$\bar{z} = n^*(\sum \epsilon_i / n)^{1/2}$$

in which $n^*=2$, n is the number of electrons in the L shell, and the ϵ_i are the successive ionization potentials of the L shell expressed in E_H units. It is of interest to have a table of \bar{z} for all the ions, as this relation will probably hold for the stripped atoms as well as for the neutral atoms. These are given in Table II. The \bar{z} 's of F and Ne are extrapolated, as well as of the negative ions.

When more than one electron is in the L shell, \bar{z} is seen to increase in steps of unity as the nuclear charge is increased. The addition of each electron after the first $2p$ electron reduces \bar{z} by 0.35.

** R. A. Millikan and I. S. Bowen, Proc. Nat. Acad. **13**, 531, (1927)INTEGRATION OF J

Upon the introduction of

$$H = \sum h_i(x_i) + \sum 2/r_{ij}$$

$$h_i = -\Delta_i + 2N/r_i \quad (2)$$

into (1) we see that J can be reduced to a function of the integrals

$$g = \int_0^\infty u(1/x)u(s/x)dx$$

$$h_n^m = \int u(m/x)hu(n/x)dx \quad (3)$$

$$K_{nq}^{mp} = \int u(m/x_1)u(n/x_1)\frac{2}{r_{12}}u(p/x_2)u(q/x_2).$$

To facilitate this reduction we define

$$U(P) = PU(1) = Pu(1/x_1)u(1/x_2)u(s/x_3) \dots$$

$$\Delta(P) = P\Delta(1) = P\delta(-\frac{1}{2}/m_{s_1})\delta(\frac{1}{2}/m_{s_2})\delta(-\frac{1}{2}/m_{s_3}) \dots$$

$$D(P', P'') = \sum_{m_{s_i}} \Delta(P')\Delta(P'').$$

The numerator of (1) becomes

$$\frac{1}{n!} \sum_{m_{s_i}} \int \left\{ \sum_{P'} (-1)^{\sigma_{P'}} P' U(1) \Delta(1) \right\} \cdot H \cdot \left\{ \sum_{P''} (-1)^{\sigma_{P''}} P'' U(1) \Delta(1) \right\} d\tau$$

$$= \frac{1}{n!} \sum_{P'} P' \sum_{m_{s_i}} \int U(1) \Delta(1) H \sum_P (-1)^{\sigma_P} P U(1) \Delta(1) d\tau$$

where $P' \cdot P = P''$, and hence $(-1)^{\sigma_{P'} + \sigma_{P''}} = (-1)^{\sigma_P}$.

Since the integrals and summation are independent of P' , and since there are in all $n!$ permutations, the numerator reduces to

$$\int U(1) H \sum_P (-1)^{\sigma_P} D(1, P) P U(1) d\tau. \quad (4)$$

Similarly the denominator becomes

$$\int U(1) \sum_P (-1)^{\sigma_P} D(1, P) P U(1) d\tau.$$

Observing that $D(1, P)$ vanishes whenever two electrons with opposite spin are permuted, and that $u(1/x)$ is orthogonal to $u(a/x)$, $u(b/x)$ and $u(c/x)$, the denominators for Be and the succeeding atoms reduce to

$$\int U(1) [1 - (13)] [1 - (24)] U(1) d\tau$$

$$= \left(\int u(1/x_1) u(s/x_3) [1 - (13)] u(1/x_1) u(s/x_3) dx_1 dx_3 \right)^2 \quad (5)$$

$$= (1 - g^2)^2.$$

Here the operator interchanging electrons i and j has been denoted by (ij) .

Putting (2) into (4) and using (5) gives the J 's for the various atoms in terms of the integrals (3).

$$J_{Be} = 2(h_1^1 + h_s^s - 2gh_s^1)/(1 - g^2) + [K_{11}^{11} + K_{ss}^{ss} + 2(2 - g^2)K_{1s}^{1s} \\ + (-2 + 6g^2)K_{ss}^{11} - 4g(K_{1s}^{11} + K_{ss}^{1s})]/(1 - g^2)^2$$

$$J_B = J_{Be} + h_a^a + [2K_{1a}^{1a} + 2K_{sa}^{sa} - K_{aa}^{11} - K_{aa}^{ss} + 2gK_{aa}^{1s} - 4gK_{sa}^{1a}]/(1 - g^2)$$

$$J_c^3P = 2J_B - J_{Be} + K_{ab}^{ab} - K_{bb}^{aa}$$

$$J_N^4S = 3J_B - 2J_{Be} + 2K_{ab}^{ab} - 2K_{bb}^{aa} + K_{aa}^{aa} - K_{cc}^{aa}$$

$$J_0^3P = 4J_B - 3J_{Be} + 3K_{ab}^{ab} - 2K_{bb}^{aa} + 3K_{aa}^{aa} - K_{cc}^{aa}$$

$$J_F^2P = 5J_B - 4J_{Be} + 4K_{ab}^{ab} - 2K_{bb}^{aa} + 6K_{aa}^{aa} - 2K_{cc}^{aa}$$

$$J_{Ne}^1S = 6J_B - 5J_{Be} + 8K_{ab}^{ab} - 4K_{bb}^{aa} + 6K_{aa}^{aa} - 2K_{cc}^{aa} + K_{bb}^{bb}$$

These expressions are the same as those given by Peierls⁷ except that he has assumed $g=0$ and the equivalence of such integrals as K_{ab}^{ab} and K_{aa}^{aa} .

COMPARISON OF ENERGY VALUES

A comparison of the observed energy required to strip the L shell in Be, B, C with the calculated energy of the L shell gives a measure of the approp-

⁷ R. Peierls. Zeits. f. Physik 55, 738 (1929).

riateness of our functions in representing the actual eigenfunctions. This is given in Table III.

TABLE III. *Energy of L shell in volts.*

	Li*	Be	B	C
obs.	5.37	27.64	70.3	145.2
calc.	5.32	25.86	68.1	142.7
error	.05	1.8	2.2	2.5

* Taken from Guillemin and Zener, reference 4.

The calculated energy of the L shell is to be defined as the minimum of J minus the calculated energy of the unperturbed K shell⁸

$$E_K = -2(N - 5/16)^2. \quad (6)$$

The calculated energies of the remaining L shells are 258.3, 417.8, 633.5, 919.0 volts for N, O, F, Ne, respectively. A comparison with extrapolated values of the empirical energies gives decidedly worse agreement.

It was found that in a series of ions, such as Be, B⁺, C⁺⁺, the discrepancy remains nearly constant between the empirical energies and those calculated from simple analytic functions. The helium series is of particular interest, where the energy⁶ is given by the function

$$\psi = g_h e^{-(N-5/16)(r_1+r_2)}.$$

TABLE IV. *Energy of helium-like ions (volts.)*

	He	Li	Be
obs	78.59	197.05 ^a	369.58 ^a
Calc.	77.05	195.44	367.94
Error	1.54	1.61	1.64

The multiplet separations have been calculated by the method given by Slater.⁵ They are from 1.5 to 2 times too large.

SUMMARY

Approximate solutions for the normal states of the elements in the first row have been calculated. The parameters in these solutions were either found to have nearly fixed values ($n^*=2$, $\gamma=N-5/16$, $\alpha \approx 0$), or values nearly equal to empirical quantities ($\delta = \bar{z}$). It is to be expected that these parameters will behave similarly in the ions of these atoms. By means of a table which is given for the \bar{z} of the various ions, one may thus write an approximate solution for all the ions, positive and negative, of the atoms in the first row. α will, however, become of increasing importance as the positive charge of the ions increases.

The writer wishes to express his gratitude to Professors Slater and Hartree for illuminating discussions. He also wishes to thank Harvard University for a Sheldon Fellowship which has enabled him to complete this work.

ATOMIC SHIELDING CONSTANTS

By J. C. SLATER

JEFFERSON PHYSICAL LABORATORY, HARVARD UNIVERSITY

(Received May 26, 1930)

ABSTRACT

In analogy with the method of Zener for the atoms from Li to F, simple rules are set up giving approximate analytic atomic wave functions for all the atoms, in any stage of ionization. These are applied to x-ray levels, sizes of atoms and ions, diamagnetic susceptibility, etc. In connection with ferromagnetism it is shown that if this really depends on the existence of incomplete shells within the atoms, rather far apart in the crystal, then the metals most likely to show it would be Fe, Co, Ni, and alloys of Mn and Cu (Heusler alloys).

IT IS often extremely useful to have simple approximations to the wave functions and energy levels of atoms and ions. Zener¹ has derived such functions for the atoms up to F, fixing the values of his parameters by variation methods. In the present paper, the functions are tentatively extended to the other atoms. The shielding constants and other parameters are not fixed by variation methods, but adjusted merely to get agreement with empirical values of stripped atom and x-ray energy levels, sizes, etc., so that the values do not have the certainty of Zener's calculations. It is to be hoped that eventually a variation calculation can be made here too; but we may anticipate that the figures given in this paper will be substantially verified, and in the meantime, an approximate set of functions is much better than none. The principal set of shielding constants which now exists is that of Pauling,² and it is believed that the present set is simpler, more general, and more accurate. The density functions derived from the present shielding constants agree fairly well with those found by Hartree's method, in cases where that has been carried out.

THE WAVE FUNCTIONS

The nodes in the wave function are found by Zener to be unimportant, and a glance at Hartree's distribution, say for Rb^+ , shows that they come much nearer the nucleus than for hydrogen wave functions, and are therefore less important. Consequently we neglect them entirely, taking as the radial part of the wave function of one electron simply

$$r^{n^*-1}e^{-(Z-s)/n^*r},$$

the asymptotic form at large distances for a hydrogen-like wave function of quantum number n^* in the field of a nuclear charge $(Z-s)$. Here Z is sup-

¹ C. Zener, *Phys. Rev.* **36**, 51 (1930); Guillemin and Zener, *Zeits. f. Physik* **61**, 199 (1930).

² Linus Pauling, *Proc. Roy. Soc. A* **114**, 181 (1927).

posed to be the actual charge on the nucleus, and s is a screening constant. We assign values of n^* , the effective quantum number, and $Z-s$, by simple rules, to the electrons in each shell in each atom or ion, and so have a complete set of one-electron wave functions. The method of combining such one-electron wave functions into functions for the whole atom has been described elsewhere.³

The values of n^* and $(Z-s)$ are given by the following rules:

(1) n^* is assigned by the following table, in terms of the real principal quantum number n :

$$\begin{aligned} \text{for } n &= 1, 2, 3, 4, 5, 6 \\ n^* &= 1, 2, 3, 3.7, 4.0, 4.2 \end{aligned}$$

(2) For determining $Z-s$, the electrons are divided into the following groups, each having a different shielding constant: $1s$; $2s, p$; $3s, p$; $3d$; $4s, p$; $4d$; $4f$; $5s, p$; $5d$; etc. That is, the s and p of a given n are grouped together (as Zener has done), but the d and f are separated. The shells are considered to be arranged from inside out in the order named.

(3) The shielding constant s is formed, for any group of electrons, from the following contributions:

(a) Nothing from any shell outside the one considered.

(b) An amount 0.35 from each other electron in the group considered (except in the $1s$ group, where 0.30 is used instead).

(c) If the shell considered is an s, p shell, an amount 0.85 from each electron with total quantum number less by one, and an amount 1.00 from each electron still further in; but if the shell is a d or f , an amount 1.00 from every electron inside it.

As a first example, we take C, $Z=6$. Here we have two $1s$ electrons, four $2s, p$ electrons. For effective nuclear charge, $Z-s$, we have

$$\begin{aligned} 1s: 6 - 0.30 &= 5.70 && \text{(Zener has 5.6875)} \\ 2s, p: 6 - 3(0.35) - 2(0.85) &= 3.25 && \text{(Zener has } 1.59 \times 2 = 3.18) \end{aligned}$$

As a second example, we take Fe, $Z=26$. There are two $(1s)$'s, eight $(2s, p)$, eight $(3s, p)$, six $(4d)$, two $(4s)$. The effective nuclear charges are

$$\begin{aligned} 1s: 26 - 0.30 &= 25.70 \\ 2s, p: 26 - 7(0.35) - 2(0.85) &= 21.85 \\ 3s, p: 26 - 7(0.35) - 8(0.85) - 2(1.00) &= 14.75 \\ 3d: 26 - 5(0.35) - 18(1.00) &= 6.25 \\ 4s: 26 - 1(0.35) - 14(0.85) - 10(1.00) &= 3.75. \end{aligned}$$

Finally we take Fe, lacking a K electron, so that there is only one $(1s)$, but otherwise it is as before. Then

$$\begin{aligned} 1s: 26.00 \\ 2s, p: 26 - 7(0.35) - 1(0.85) &= 22.70 \\ 3s, p: 26 - 7(0.35) - 8(0.85) - 1(1.00) &= 15.75 \\ 3d: 26 - 5(0.35) - 17(1.00) &= 7.25 \\ 4s: 26 - 1(0.35) - 14(0.85) - 9(1.00) &= 4.75. \end{aligned}$$

³ J. C. Slater, Phys. Rev. **34**, 1293 (1929).

THE ENERGY VALUES

The total energy of an atom or ion—the negative of the energy required to remove all electrons from the nucleus to an infinite distance—is found by Zener to be accurately given by the sum of the quantities— $((Z-s)/n^*)^2$ for all electrons of the atom (This is the significance of his connection of the shielding constant with the empirical “mean effective charge”). This is very reasonable. If we take as an atomic wave function a product of one-electron wave functions of our type, for each electron, then allow the energy operator to act on it, the result will consist of several parts, as one can readily verify: (1) the sum of $-((Z-s)/n^*)^2$ for each electron, times the function, coming from the second derivative in the Laplacian operator; (2) terms in $1/r$, and higher powers, times the function, coming from the Laplacian; (3) terms in $1/r$, times the function, coming from the potential energy. For the correct wave function, (2) and (3) will cancel each other, leaving just terms (1), a constant times the function, so that Schrödinger’s equation will be satisfied. It seems very reasonable that, in a wave function which is a good approximation, this will be nearly the case too. But this leaves as the energy just the sum which we have mentioned. We therefore take that as giving the energy of an atom or ion, saving ourselves by this simple rule from the necessity of computing the energy by the usual method of integrating H . This of course gives the energy in terms of the Rydberg energy.

As a first example, we take the energy required to remove all the L electrons from C . We have

$$\text{normal atom: } -2(5.70)^2 - 4(3.25/2)^2 = -64.98 - 10.56 = -75.54$$

$$\text{atom with } L \text{ electrons stripped off: } -2(5.70)^2 = -64.98$$

$$\begin{aligned} \text{Difference} &= \text{energy of removal} = 10.56 = 10.56 \times 13.56 \text{ volts} \\ &= 143.2 \text{ volts (correct, 145.2; Zener has 142.7)} \end{aligned}$$

As a second example, we take the energy required to remove any electron from the Fe atom, We have

$$\begin{aligned} \text{normal atom: } &-2(25.70)^2 - 8(21.85/2)^2 - 8(14.75/3)^2 - 6(6.25/3)^2 - 2(3.75/3.7)^2 \\ &= -2497.2 \end{aligned}$$

$$\begin{aligned} \text{atom lacking one } 1s \text{ electron: } &-1(26.00)^2 - 8(22.70/2)^2 - 8(15.75/3)^2 \\ &- 6(7.25/3)^2 - 2(4.75/3.7)^2 = -1964.6. \quad \text{Difference} = 532.6; \text{ observed} \\ &K \text{ absorption limit} = 524.0 \end{aligned}$$

$$\begin{aligned} \text{atom lacking one } 2s, p \text{ electron: } &-2(25.70)^2 - 7(22.20/2)^2 - 8(15.60/3)^2 \\ &- 6(7.25/3)^2 - 2(4.75/3.7)^2 = -2437.7. \quad \text{Difference} = 59.4; \text{ observed } L \text{ ab-} \\ &\text{ sorption limits, } L_{11} = 61.9, L_{21} = 53.4, L_{22} = 52.4 \end{aligned}$$

$$\begin{aligned} \text{atom lacking one } 3s, p \text{ electron: } &-2491.1; \text{ difference} = 6.1; \text{ observed } M_{11} \\ &= 7.07; M_{21}, M_{22} = 4.2 \end{aligned}$$

$$\begin{aligned} \text{atom lacking one } 3d \text{ electron: } &2496.4; \text{ difference} = 0.8; \text{ observed energy of} \\ &\text{ removal of } 3d \text{ electron from } Fe \text{ atom, by Moseley law in optical spectra,} \\ &0.8 \end{aligned}$$

$$\begin{aligned} \text{atom lacking one } 4s \text{ electron: } &2496.3; \text{ difference} = 0.9; \text{ observed energy of} \\ &\text{ removal of } 4s \text{ electron} = 0.58 \end{aligned}$$

It is interesting to notice in this example how the so-called "outer shielding" of the x-ray terms comes about, by the decrease of the shielding constants of the outer electrons when an inner electron is removed. It is also interesting to see how this rearrangement of shielding constants brings it about that the 3*d* electrons, although much further in than the 4*s*, still require about the same energy for their removal.

As a final example, we take the ionization potential of the alkalis:

normal Li: energy of *K* shell $-(1.30/2)^2$ = energy of *K* shell -0.423

ionized Li: energy of *K* shell; difference = 0.423; observed ionization potential = 0.397.

We observe that we can get these ionization potentials directly, without considering the inner shells. Thus we have for the ionization potentials:

$$\text{Na } (2.20/3)^2 = 0.537, \text{ observed} = 0.378$$

$$\text{K } (2.20/3.7)^2 = 0.354, \text{ observed} = 0.319$$

$$\text{Rb } (2.20/4.0)^2 = 0.302, \text{ observed} = 0.307$$

$$\text{Cs } (2.20/4.2)^2 = 0.274, \text{ observed} = 0.287$$

The examples which we have worked out are a fair sample of the energies obtained in general from the scheme; one sees that they are qualitatively accurate, though by no means to be trusted in detail. The principal criterion used in setting up the rules for the shielding constants has been to make the energy check fairly well with experiment.

SIZES OF ATOMS AND IONS

The maximum of the radial charge density for one of our shells comes, as we immediately find by differentiation, at $(n^*)^2/(Z-s)$. Thus our shielding constants permit us to compute the sizes of atoms and ions. For example, the radius, as defined in this way, of the outer, 4*s* shell of Fe is $(3.7)^2/3.75 = 3.65 = 1.95$ Angstroms. The radii of the outer shells, defined in this way, can be brought into interesting connection with the internuclear distances in valence compounds and in metals, in which the substances exist in the atomic state. For binding, we should expect that the electrons forming the bond would wish to have the maximum possible overlapping, which would come if the internuclear distance were the sum of the radii so defined, so that the maxima of density lay together. As a matter of fact, this is closely the case, when the valence electrons are *p* electrons; but when both valences are *s* electrons, the distances are smaller, about 2/3 of this. In any case, the correlation is quite good, and should be useful in predicting approximate internuclear distances where they are not known. We give, in Table I, the atomic radii so derived, and in Table II a number of internuclear distances, as observed in band spectra and crystals, together with the sum of the theoretical radii for comparison, and the ratio of the two. These ratios are, as we stated, about 1 when one or both valences are *p* electrons, but about 2/3 when both are *s* electrons. In a few cases, such as the hydrogen halides, where one might suppose the substances to be ionic rather than valence

compounds, the excellent agreement with our rule gives us confidence that the valence bond essentially describes the situation.

TABLE I. *Atomic radii (Angstroms).*

(These radii are the radii of the values for maximum radial density in the charge distributions of the outer shells of the neutral atoms, computed from the effective quantum numbers and effective nuclear charges by the formula $(n^*)^2/(Z-s)$.)

In studying valence, we are interested in the size of the outer shell, but for ferromagnetism the essential, as the writer has shown in an earlier paper,⁴ is the existence of an inner shell in process of formation, small enough so that the distance of separation is relatively great compared with the size of the shell. To see what metals should show ferromagnetism, if this idea is correct, we also give in Table II the radii for the d shells in process of formation in the transition groups, and the ratio of internuclear distance to twice this radius. This ratio is greater for Fe, Co, and Ni than for any other element, so that these would be most likely to be ferromagnetic. We might suppose that as two such shells were moved apart, the interaction was nonferromagnetic (the terms of lowest multiplicity lying lowest) out to about 1.55 times the sum of the radii; there the interaction would change sign, passing through a critical region (suggesting the fact that Mn sometimes shows magnetic properties, usually not). The first element beyond the critical region, Fe, would show the greatest ferromagnetism. As the internuclear distance still further increased, the exponential dropping off of the wave function would make the interaction less, resulting in weaker effects in Co and Ni. These conclusions are made much more reasonable by considering the Heusler alloys. Here Cu takes the place of Mn in an alloy with Al or other substance, and the alloy is almost as ferromagnetic as Fe. Now if Cu can replace Mn, it is presumably in a form with two $4s$ electrons, nine $3d$'s so that it has an open shell of d electrons, which is even smaller than for Ni (radius = $1.17/2A$). This very small radius, added to the large radius of Mn, gives a sum of $1.44A$, and a ratio intermediate between Fe and Co, suggesting a strong ferromagnetism, although Mn by itself is too big, Cu too small (and in ordinary Cu undoubtedly the $3d$ shell is closed anyway) to show ferromagnetic properties.

In ionic compounds, the atoms exist as ions, which have closed shells; and the interionic forces are repulsions (except for the electrostatic attractions), and account for the hardness and impenetrability of the structures. These repulsions become large, as has often been shown, as soon as the outer shells begin to overlap, and the internuclear distances in ionic crystals should be the sums of radii representing, not the radius of maximum density in the shell, but a considerably larger radius at which the charge just begins to become

⁴ J. C. Slater, Phys. Rev. 35, 509 (1930).

appreciable. It appears that the appropriate radius is roughly one at which the radial density becomes 10 percent of its maximum value. By solving the problem numerically, we find that for the density function we have used, this radius is a numerical factor times the radius of maximum density, this factor being 3.38 for $n^*=1$, 2.49 for $n^*=2$, 2.25 for $n^*=3$, 2.01 for $n^*=3.7$, 1.96 for $n^*=4.0$. Thus, finding the radius of maximum density, now for the ion rather than for the atom, and using these factors to get radii of 10 percent density, we get the ionic radii given in Table III. They should be compared with the ionic radii of Wasastjerna, which are to be added to give grating spaces, and which are also tabulated. It is seen that the agreement in general is decidedly good. This renders it highly probable that the atoms really exist in these compounds as ions, as has been supposed. Computed values are included for the inert gases, and these should be the radii of these gases, as derived in the kinetic theory. The latter of course vary over a considerable range, but our values seem to lie well within this range in each case. For example, for He, Jeans in his "Dynamical Theory of Gases" gives values from 0.99A to 1.10A, as determined by various methods; our value is 1.05A.

TABLE III. *Ionic radii (Angstroms).*

(Observed radii as given by Wasastjerna; see for instance W. L. Bragg, *Phil. Mag.* 2, 258 (1926); the sum of these radii gives the interionic distance in ionic crystals. Calculated values are for radius where density is 10% of its maximum value. This equals constant times $(n^*)^2/(Z-s)$, where the constant equals 3.38 for $n^*=1$, 2.49 for $n^*=2$, 2.25 for $n^*=3$, 2.01 for $n^*=3.7$, 1.96 for $n^*=4.0$)

Ion	Observed	Calculated	Ion	Observed	Calculated
H ⁻		2.57	Se ⁻		2.34
He		1.05	Br ⁻	1.92	2.02
Li ⁺	0.76	.67	Kr		1.77
Be ⁺⁺	(.3)	.49	Rb ⁺	1.50	1.58
			Sr ⁺⁺	1.20	1.43
O ⁼	1.32	1.37	Te ⁼		2.66
F ⁻	1.33	1.09	I ⁻	2.19	2.30
Ne		.91	Xe		2.02
Na ⁺	1.01	.77	Cs ⁺	1.75	1.80
Mg ⁺⁺	.75	.67	Ba ⁺⁺	1.40	1.62
Al ⁺⁺⁺	(.55)	.60			
Si ⁴⁺	(.3)	.54			
S ⁼	1.69	2.16			
Cl ⁻	1.72	1.79			
A		1.52			
K ⁺	1.30	1.33			
Ca ⁺⁺	1.02	1.17			

We can get a valuable check on the size of atoms by using the diamagnetic susceptibility, which is proportional to the mean value of Σr^2 . From our wave functions, by integration we find this quantity for one of the electrons to be $(n^*)^2 (n^*+1/2) (n^*+1)/(Z-s)^2$. For the inert gases, we have the following values:

	computed	observed
He	2.07	2.34
Ne	7.08	8.31
A	23.37	22.6

A SEARCH FOR THE SOURCE OF DIELECTRIC POLARIZATION

BY RALPH D. BENNETT

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received May 23, 1930)

ABSTRACT

A brief discussion is given of the work of Hengstenberg on the same subject. A theory of the distortion of a polar cubic lattice by electric stress is derived with the method suggested by Richardson for calculating electric stress on the ions, and the frequency of residual rays for determining the restraining forces. The effect of the distortion on intensity of x-ray reflection is then calculated in the usual manner. Measurements of change in intensity of reflected x-rays were made with a precision of about 0.1 percent in the 4th and 5th orders for NaCl and the 5th order for KCl using gradients up to 700 kv/cm. It is concluded that the effect is probably not as large as predicted by Hengstenberg, i.e., the polarization is probably not due to motion of the ions as units. The precision of the experiments was not high enough to determine whether the theory derived here is correct.

IF A polar crystal is subjected to electric stress the positive and negative ions might be expected to be displaced in opposite directions. The distorted lattice would then reflect x-rays less intensely than before distortion. J. Hengstenberg¹ has derived a theory of this effect based on the assumption that the total polarization is due to the displacement of the ions as units. This assumption seems hardly justified since the polarization effects exhibited by nonpolar substances are of the same order of magnitude as those of polar substances. However Hengstenberg has tested his theory for KCl and found the experimental results in agreement.

A calculation of the electrostatic force due to an external field on an ion in a crystal of this type can be made following the method suggested by Richardson.² By considering the forces due to the condenser charge, the polarization charge, and the doublets in the neighborhood of the ion, the following equation is obtained:

$$f_e = \frac{K + 2}{3K} Ee \text{ dynes} \quad (1)$$

where K is the dielectric constant, E the field in e.s.u. per cm, and e is the electronic charge in e. s. u.

The binding forces on the atoms in a crystal can be calculated if we assume their resonance frequency to be that of the residual rays. The differential equation is:

$$m\ddot{x} + qx = 0$$

where m is the mass of the atom and q the restoring force per unit displacement.

¹ J. Hengstenberg, *Zeits. f. Phys.* **58**, 345 (1929).

² O. W. Richardson, *Electron Theory of Matter* p. 71 *et seq.*

A solution of the equation is:

$$x = A \cos (pt + \theta)$$

where

$$p = (q/m)^{1/2} = 2\pi\nu = 2\pi c/\lambda$$

λ being the resonance wave-length and c the velocity of light.

Then

$$q = 4\pi^2 c^2 m / \lambda^2 \text{ dynes/cm}$$

or for a displacement of δ cm

$$f_\delta = 4\pi^2 c^2 m \delta / \lambda^2. \quad (2)$$

If the binding forces for $\lambda = \infty$ are not substantially different from those for the wave-lengths of the residual rays then $f_\delta = f_e$ or combining Eqs. (1) and (2)

$$\frac{K+2}{3K} Ee = 4\pi^2 c^2 m \delta / \lambda^2$$

whence

$$\delta = \frac{\lambda^2}{4\pi^2 c^2 m} \frac{K+2}{3K} eE \quad (3)$$

If the lattice is distorted by moving alternate atoms in opposite directions in a cubic crystal, the intensity of the x-rays reflected may be shown to be:³

$$I_\delta = I_0 \cos^2 2\pi n \delta / D$$

where I_δ = intensity from distorted lattice

I_0 = intensity from undistorted lattice

n = order of reflection

δ = distance through which each atom is moved

D = distance between adjacent atomic layers.

The fractional change in intensity due to distortion is then:

$$\frac{\Delta I}{I} = \frac{I_0 - I_\delta}{I_0} = 1 - \cos^2 2\pi n \delta / D = \sin^2 2\pi n \delta / D$$

and for small values of δ

$$\frac{\Delta I}{I} = (2\pi n \delta / D)^2. \quad (4)$$

Combining Eqs. (3) and (4)

$$\frac{\Delta I}{I} = \left[\frac{(K+2)\lambda^2 n e}{6\pi K m c^2 D} \right]^2 E^2.$$

³ cf. A. H. Compton, X-rays and Electrons Chap. V.

With the values $e = 4.77 \times 10^{-10}$, $c = 3 \times 10^{10}$ and for NaCl

$$K = 6.12$$

$$\lambda = 52 \times 10^{-4} \text{ cm}$$

$$D = 2.81 \times 10^{-8} \text{ cm}$$

$$m = 23.00 + 35.46/2 \times 6.06 \times 10^{23} = 4.84 \times 10^{-23} \text{ grams}$$

and for KCl

$$K = 5.03$$

$$\lambda = 63.4 \times 10^{-4} \text{ cm}$$

$$D = 3.14 \times 10^{-8} \text{ cm}$$

$$m = 39.10 + 35.46/2 \times 6.06 \times 10^{23} = 6.18 \times 10^{-23} \text{ grams.}$$

For the 4th order NaCl $\Delta I/I = 0.89 \times 10^{-11} E^2$.

For the 5th order NaCl $\Delta I/I = 1.40 \times 10^{-11} E^2$.

For the 5th order KCl $\Delta I/I = 1.68 \times 10^{-11} E^2$.

These values are plotted in the dotted curves of figs. 3, 4 and 5. The corresponding values obtained from Hengstenberg's equations are represented by the dashed lines. The difference between these predictions would seem to be due to Hengstenberg's neglect of possible distortion of the ion under the influence of the applied electric field.

EXPERIMENTAL ARRANGEMENT

The source of x-rays was a water-cooled Coolidge molybdenum target tube immersed in oil and operated at from 30 to 45 ma. and 40 to 50 peak k. v. by a full wave rectifier. The crystals under test were mounted on the table of a spectrometer which also carried an arm for supporting the ionization chamber. The ionization currents were measured by means of a screen grid amplifier described in detail elsewhere,⁴ the variations in the plate current being measured by a galvanometer. A record of the galvanometer deflection was traced photographically on bromide paper, which was drawn at a constant rate by a synchronous-motor-driven reduction gear.

The crystals were mounted in a manner essentially the same as that used by Hengstenberg. This consisted of splitting the crystal as thin as conveniently possible, then mounting by means of sealing wax over a hole of about 7 mm diameter in a glass plate. After mounting, the crystal can be reduced to the desired thickness by washing with water. The thickness of the crystals used ranged from about 0.25 to 0.40 mm, a rough measurement being made by means of a dial test indicator before use, and more exactly by micrometer calipers after puncture. A circular piece of very thin aluminum foil was cemented with shellac to each side of the crystal for applying the electric stress.

The source of voltage for the crystals consisted of a kenotron rectifier set with a condenser, and could supply up to 21 k.v. direct current. This source was connected to the back foil of the crystal through a resistance of several megohms, the foil on the reflecting side being grounded. The high

⁴ R. D. Bennett, An Amplifier for Measuring Small Currents Rev. of Sci. Inst. in press.

voltage was switched on and off by means of a kenotron which when the filament was lighted served to ground the back surface of the crystal. The kenotron filament was switched by the same mechanism that moved the photographic paper, and an auxiliary light traced a record on the paper whenever the kenotron filament was lighted. The amplifier for the ionization

Fig. 1. Diagram of apparatus.

current was so sensitive to high frequency surges that this method of switching was necessary. For the same reason sources of sparking in the x-ray supply circuit had to be removed. Voltage on the crystal was measured by means of a spark gap. Fig. 1 is a diagram of the circuits.

The amplifier arrangement reads the ionization current directly, and the electrostatic capacity of the collector is so small that the ionization from the

Fig. 2.

individual photoelectrons produces variations in the plate current. This makes the galvanometer trace a wavy line, the fluctuations being of the order of 1 percent in the arrangement used. Hence it was necessary, in order to measure to higher precision than 1 percent to take an average over a number of intervals. The method of analysis of the records is best shown by Fig. 2. The trace *A* is a calibration curve obtained by alternately inserting and removing a screen which absorbs a_0 percent of the x-ray beam. The sum of the areas 1, 3, 5 etc. is measured by means of a planimeter and an average area

s_0 found. From this is subtracted the average of the even areas s_e . Then $s_0 - s_e/a_0 = s_1$ gives the average area difference equivalent to 1 percent change in intensity. The curve B which is made with the field alternately on and off is then analysed in the same manner giving an average difference, say s_2 . Then the ratio s_2/s_1 gives the fraction of 1 percent change due to the field. The precision of the result will be proportional to the square root of the num-

Fig. 3.

Fig. 4.

ber of periods averaged. Each period was 44.4 seconds, and approximately the first third of each interval was omitted to allow for adjustment of the recording system to a new value of ionization current.

Observations were made in the 4th and 5th order for rock salt and the 5th order for sylvine, the gradients ranging up to 700 k.v./cm. The tests under different gradients were grouped together in 100 k.v./cm. ranges, and the results are plotted in Figs. 3, 4 and 5.

The sensitivity of the apparatus was such that $1/30$ of one percent in the 5th order could just be detected if the deflection were steady. However to reduce the fluctuations to this level it would be necessary to increase the

Fig. 5.

ionization current by a factor of $[1/(1/30)]^2 = 900$ which would hardly be possible. Increasing the electrostatic capacity of the recording system would be of no avail because there were irregular line voltage variations of about 1 percent.

CONCLUSIONS

The experimental results are not precise enough to tell definitely whether Hengstenberg's theory, the theory outlined above, or neither describes the effect. The 700 k.v./cm point on the 5th order NaCl curve falls very nearly at the value predicted by Hengstenberg's theory. It is doubtful whether this is more than a coincidence since it depends on a small number of observations. No other crystal stood this high field though many attempts were made to find one. The writer believes that from consideration of all the data, the effect is probably not as large as predicted by the Hengstenberg theory.

The KCl crystals used were very kindly furnished by Dr. E. F. Barker of the University of Michigan. I am also indebted to Professor A. H. Compton for advice and interest in this problem. The work was supported by the Utilities Research Commission as a part of their program of investigation of the properties of solid dielectrics at Ryerson Laboratory of the University of Chicago.

INFRARED FILTERS OF CONTROLLABLE TRANSMISSION

BY A. H. PFUND

ROWLAND HALL, JOHNS HOPKINS UNIVERSITY

(Received May 26, 1930)

ABSTRACT

When using an echelette grating for work in the infrared it is necessary to eliminate overlapping, higher orders. Since no adequate series of true filters covering the entire infrared is known, a new type of filter has been developed. Essentially, this type of filter consists of a powder spread uniformly over a surface of polished speculum. Short wave-length radiations are reflected diffusely while long wave-length radiations are largely transmitted since the Rayleigh scattering for long waves is feeble. The region of transition from opacity to transparency is controlled by choosing powders of proper particle-size and by depositing these in layers of appropriate thickness.

Specific examples, involving the use of particles whose mean diameter covers the range: 0.22μ to 2.5μ , are presented to show how filters for almost any portion of the spectral range: 2μ to 7.5μ may be largely freed from the effects of superposed, higher orders. Filters for greater wave-lengths may be produced by much the same methods.

FOR the attainment of large dispersion and high resolving-power in the infrared, the diffraction grating, in particular, the echelette grating is coming into wide use. It suffers, however, from one drawback, i.e. superposed orders. If for example, an echelette grating be adjusted for work in the first order near 3μ , there is superposed on this a large amount of second order 1.5μ energy, third order 1μ energy, etc. Due to the fact that the usual Nernst lamp has its energy maximum near 1.6μ , the energy of the contaminating radiations exceeds greatly the energy at 3μ . It is proposed to discuss in the following a new type of filter which, though by no means perfect, does minimize the effect of contaminating radiations.

The term filter is here employed in the broad sense of being a device which either isolates narrow spectral regions or which experiences a change from opacity to transparency within a relatively small wave-length interval. To be specific, a satisfactory filter for an echelette grating, operating between the limits 3μ to 3.5μ , would be one which is quite opaque for all radiations shorter than 1.75μ and quite transparent for radiations greater than 3μ . To realize so great a change in transparency within so narrow a spectral range is difficult.

Methods now in use for filtering out the undesirable radiations are here enumerated: I. Infrared monochromator.¹ II. Residual rays.² III. Reflection from rough surfaces.³ IV. True absorption filters.⁴ Without going

² Rubens and Aschkinass, *Ver. deutsch phys. Ges.* **17**, 42 (1898).

³ Gorton, *Phys. Rev.* **7**, 66 (1916).

⁴ Coblenz, *Supplementary Investigations of Infrared Spectra 5-7*, Carnegie Inst. of Washington (1908).

A very comprehensive list of references, dealing with the infrared, is to be found in "Le Spectre Infrarouge" by Jean Lecomte, Les Presses Universitaires de France (1928).

into a detailed discussion of the various devices it may be stated that most of them are limited in the range of spectrum which can be covered; again, some lack flexibility, i.e. if true filters or crystals (employed for residual rays) fail to show high transmission or reflection, respectively, in the region to be studied, there is nothing to be done about it. As for reflection from rough surfaces it may be said that the wave-length interval separating regions of low and high reflection is entirely too great to be considered seriously for the present purpose.

The new filters about to be described are a by-product of some work that is being carried out on the measurement of particle-size of finely divided powders by studying their transmission in the infrared. Rayleigh's inverse fourth power law of scattering is strictly applicable only if the particle-size be small in comparison with the wave-lengths employed. If, however, the particle-size be large in comparison with the wave-length, the particles assume the role of small mirrors which reflect vigorously. Consequently, if transparent particles of a uniform and suitable size be produced it will be found that they reflect the regions of short wave-lengths strongly and scatter those of great wave-length feebly. Used in transmitted light a film of such small particles will be virtually opaque to the short wave-lengths and highly transparent to the longer. Body-color, involving true absorption, plays no necessary part in the functioning of these filters.

The pulverized materials used in the construction of such filters must fulfill certain necessary conditions: 1. The material must be highly transparent in the spectral region to be studied. 2. A large range of particle-sizes must be available, and the particles in any individual class must be essentially constant in size. 3. The substratum on which the pulverized film is deposited must be transparent. 4. The films must be of uniform thickness.

Concerning condition (1) it may be said that short of 20μ , oxides, sulphides and halides have been found most transparent. Thusfar the most satisfactory films have been formed by the process of "fuming" as, for example, by allowing the oxide fumes from burning magnesium ribbon to collect on a plate. Condition (2) is not as yet realized. It is to be pointed out, however, that methods for accomplishing this purpose are known. The well-known process of "air-flotation" and subsequent settling has been used. Again, the method of successive centrifugings has been employed for bringing about uniformity of particle-size. The nature of the substratum (condition 3) depends largely upon the spectral region to be studied. Microscope cover glass 0.2 mm thick will serve up to 4μ while a thin plate of rock-salt will be useful at least up to 18μ . In order to eliminate completely the element of transparency of the substratum the procedure of coating a polished speculum plate with the pulverized film has been adopted—particularly for the region of long waves. Such a mirror will reflect all wave-lengths while the film will reflect the short waves diffusely but will transmit the long ones regularly. Attention is to be drawn to the fact that, while the widest possible spectral range may be covered by using a speculum or some other reflecting surface, the performance of such a "reflection" filter is less satisfactory than that of

a transmission filter. The reason is that the diffusely reflected light of shorter λ is in part added to the regularly reflected light in the case of the reflection filter, but not so in the transmission filter.

A few examples of the performance of these filters are here presented. Measurements were carried out by means of a rock-salt spectrometer and thermopile. Since it is difficult to control the film thickness accurately, it is necessary to resort to the use of a spectrometer in order to decide when a film of the proper characteristics has been deposited. In Fig. 1 are presented "transmission" curves (*A* and *B*) for zinc-oxide which was fumed on microscope cover glass. The fumes were supplied by an arc burning between zinc

Fig. 1. Transmission curves for films of ZnO and MgO.

terminals. For the thicker film a deep, ruby-red image of an incandescent lamp filament was visible in transmitted light. A similar series for MgO, fumed on speculum is shown in curves *C*, *D* and *E* which apply to films of increasing thickness. In order to obtain the "incident energy" the oxide film was wiped off the speculum mirror.

It is known that zinc oxide particles are smaller than those of magnesium oxide. This is borne out by the curves which show that the transition region for ZnO lies at the shorter wave-lengths. While it is possible to shift this transition region somewhat in the direction of increasing wave-lengths by increasing the film-thickness, a limit is set to this mode of procedure as is evident from the decreasing slope of curve *E*, Fig. 1, in the region of high transparency. It is thus shown that, to produce filters for increasing wave-lengths, particles of increasing size must be used.

Even though a filter, as judged by its transmission curve, may appear to be entirely satisfactory, it is not necessarily so. The total energy associated with any wave-length is given by the product of the following quantities: 1. energy emitted by source. 2. transmission of total air-path. 3. reflection factor for the echelette grating, and 4. transmission factor for filter. This is illustrated in the following curves for films of increasing thickness. In Fig. 2 are plotted the true transmission coefficients of MgO plus cover glass while in Fig. 3 the actual energies are plotted for the same filters. The Nernst

lamp was operated at such a temperature as to place the wave-length of maximum emission at 1.9μ , no correction for irrationality of dispersion having been applied. It is this powerful maximum which must be rendered innocuous if regions of greater wave-length are to be studied. It is usually possible to realize any desired freedom from contamination from shorter wave-lengths; but this is accomplished at the expense of transmission. For the time being two arbitrary criteria for acceptable filters have been laid down, i.e. (1) the transmission, in the region under consideration, λ , must be at least 50%, (2) the energy at $\lambda/2$ ought not to exceed 5–10% of the energy at λ . Applying these criteria to specific filters it is evident that filter III, (Figs. 2 and 3) is

Fig. 2. Transmission curves for various thicknesses of MgO on glass of 0.2 mm thickness. Transmission of glass included in curves.

Fig. 3. Relative energies from Nernst lamp transmitted by same films shown in Fig. 2.

most satisfactory in the 3.75μ region. If a wedge-shaped film of oxide be deposited on an over-size speculum mirror, it is easy to pick out the position of the film having the best thickness. If, on the other hand, the film be deposited on microscope cover-glass the latter may be rotated about a vertical axis, thus changing the effective thickness of film, or again, a wedge-shaped film may be deposited.

While the deposition of fumed films is comparatively simple, it becomes difficult to make the thickness uniform whenever the pulverized material is furnished as a dry powder. It is proposed to form films of these materials by the well-known method of "air-flotation." For the time being, films were prepared by dispersing these pigments in water. A small amount of pigment and water were placed on a flat plate of glass and the mixture was ground to a paste of uniform consistency by means of a glass "muller." The latter was then used for applying the paste to the speculum surface. Unfortunately, films produced in this manner are non-uniform in thickness and, as a result the transition range is broadened out. While a graded series of NaCl powders would have been desirable it was found necessary to use such coarser particles as were available, despite the fact that they were known to have bands of

absorption in the region of longer waves. The series of filters shown in Fig. 4 were obtained through the use of the following powders whose respective average diameter of particle⁵ is given in Table I.

Fig. 4. Relative energies from Nernst lamp transmitted by various filters.

TABLE I.

Powder	Average particle diameter	Mode of application
I. Zinc oxide	0.22 μ	Fumed
II. Magnesium Oxide	0.35	"
III. Basic carbonate of white lead	0.50	Water Paste
IV. Silica	2.5	"

These curves for relative energies are so plotted that the maxima have approximately the same heights. Inspection shows that a very fair degree of separation between short and long waves has been effected and that, each filter may be used to advantage in the region of maximum energy. In fact it is evident that, following this general mode of procedure, a filter for almost any desired spectral region may be produced.

The sharp drop of the curve for Silica (SiO_2) near 8 μ is due to the true absorption of this material; the same may be said for the sharp drop at 7 μ for basic carbonate white lead. In this connection it may be stated that the writer has on record a large number of "transmission" curves for films of powdered sulphates and carbonates spread on polished speculum. These curves reveal a great deal more complexity than do the curves obtained by reflection from polished crystals. The results will be published at a later date.

In carrying out precise measurements with an echelette grating, together with these new filters, it is essential that the slight effect of superposed orders, higher than the first, be taken into account. To accomplish this, it is neces-

⁵ The measurements of particle-size were kindly carried out by Mr. G. S. Haslam of the Research Laboratory of the New Jersey Zinc Co.

sary to procure a series of filters whose characteristics are exactly the reverse of those already described. To be specific, if the 4μ region be studied, it is necessary to procure a filter which is entirely opaque at 4μ and highly transparent at 2μ and at all shorter wave-lengths. Fortunately, this problem is relatively simple. As is well known, layers of water, glass, quartz, fluorite, etc., when given the proper thickness, can be made to fulfill the conditions imposed on this type of filter. In this connection it is to be stated that, if nonaqueous filters be desired in the region of the near infrared, corex glass and a urea-formaldehyde condensation product known as Pollapos, are very effective. Corex glass of 3.2 mm thickness is opaque at 3μ while Pollapos of 4.5 mm thickness transmits virtually nothing at 1.6μ . It is hardly necessary to add that the effectiveness of a powder-filter can be increased by choosing a light source such that the emission of shorter wave-lengths is suppressed while that of the longer ones is enhanced as, for example, in case of the Welsbach mantle.

This report is incomplete since specific direction for powder filters covering the entire range of the infrared are not available. It is felt, however, that having described the general mode of procedure, the individual investigator will be guided in the production of filters required for his special needs.

VELOCITY OF ULTRASONIC WAVES IN WATER VAPOR

BY GEORGE E. THOMPSON
IOWA STATE COLLEGE, AMES, IOWA

(Received May 22, 1930)

ABSTRACT

The velocity of sound waves having a frequency of 108,600 cycles per second, has been measured in water vapor by a method similar to that used by Pierce for other gases. At a temperature of 27° C. the velocity is 432 meters per second.

SOME results by Pierce¹ for the velocity of ultrasonic waves in air showed much less than the expected variation of velocity with change of humidity. This situation suggested the desirability of making similar measurements in pure water vapor, so the present work was undertaken. More recently Reid² found the effect due to humidity which was expected on the basis of theory. It still seemed worth while, however, to continue the work with water vapor along the line originally planned.

DESCRIPTION OF APPARATUS

The sound chamber consisted of a cylindrical brass tube of 9.5 cm inside diameter and 25 cm in length. A plane reflector about 9 cm in diameter was moved back and forth by the calibrated screw *S*. (See Fig. 1) In order to

Fig. 1. Diagram of apparatus.

get an air tight joint at *a*, the rod carrying the reflector was enclosed in a rubber tube which was fastened to the sound chamber at *a* and to the rod at *b*. This arrangement permitted the reflector to be moved back and forth easily, the rubber being stretched or contracted to accommodate the motion of the rod. The rod was about 150 cm long. A spiral spring was placed around the rod and inside the rubber tube to keep the tube from gripping the rod when the pressure was reduced inside the chamber.

¹ G. W. Pierce, Proc. Am. Acad. of Arts and Sciences 60, No. 5 (1925).

² C. D. Reid, Phys. Rev. 35, 814 (1930).

The quartz crystal was mounted between electrodes on the end of a brass plug which was carefully ground to fit a tapered opening at the end of the chamber. The wire leading to the upper electrode of this crystal holder was insulated by filling the hole through which it passed with sealing wax. The lower electrode was not insulated from the plug so that connection to it was made by soldering a wire to the outside end of the plug.

The vapor was generated in a glass bottle *V* and pumped slowly through the chamber *C* during the course of the experiment. It was necessary to keep the pumps working continuously because the apparatus was not quite vacuum tight, the leak with the pump idle amounting to about one half centimeter of mercury pressure per hour.

The electrical circuit is fully shown in the figure and needs no detailed description. Instead of making observations on a d.c. meter placed in the plate circuit of the oscillator tube, a Weston, model 412, high frequency milliammeter (2 m.a. range) was placed in a resonant circuit which was coupled loosely with the oscillator. This circuit had a resistance of over 700 ohms and consequently tuned very broadly.

The temperature of the vapor was measured with a copper-constantan thermocouple placed in front of the crystal but above the direct path of the sound waves.

METHOD OF THE EXPERIMENT

Absolute measurement of velocity was not attempted. The velocity of the waves in air was assumed to be known and the velocity in the vapor determined by comparing the wave-length in vapor with the wave-length in air. In water vapor the crystal oscillations were somewhat irregular so that high precision of measurement could not be attained easily. Also the milliammeter fluctuations caused by the motion of the reflector were very slight due to the low density of the vapor. This difficulty was partly overcome by using a microscope to observe the movement of the pointer of the meter. In making measurements, the reflector was placed about 2.5 cm from the crystal face and at a position of minimum deflection, and the position read on the screw. Another position 20 half wave-lengths farther from the crystal was found and another reading taken. The settings were always made with the screw turning in the same direction.

SOURCE OF ERROR

It was considered likely that the greatest source of error would be the lack of purity of the vapor caused by air leakage. Consequently, extremely accurate measurement of temperature, pressure, frequency, and wave-length were not attempted.

In order that the wave-length be proportional to velocity the frequency of the crystal must not change when the nature of the surrounding gas is changed. A second oscillator was heterodyned with the crystal oscillator to give a beat note of about 200 cycles per second. Since no very appreciable change of pitch was produced by changing from air to water vapor, the frequency control was deemed satisfactory.

The screw was calibrated by comparison with a Gaertner comparator and found to be of sufficiently uniform pitch, the maximum variation from the average being about 0.009 mm. The average pitch was 2.509 mm.

RESULTS

The wave-length in air at 22°C was found to be 3.176 mm. Considering the velocity to be 345 meters per second, the frequency figures out to be about 108,600 cycles per second.

In Table I are values for the wave-length in water vapor. These are given in terms of the pitch of the screw and changed to mm after averaging.

TABLE I. *Wave-lengths in water vapor.* (Average, $1.586 \times 2.509 = 3.979$ mm, Vapor pressure, 1.4 cm of mercury, Temperature, 27°C).

1.581	1.585	1.566	1.597
1.610	1.605	1.591	1.600
1.593	1.567	1.588	1.588
1.576	1.572	1.597	1.572
1.575	1.576	1.604	1.572
1.588	1.596	1.578	

With the data of Table I, we get for the velocity of sound in water vapor at 27°C.

$$V = (3.979/3.176) \times 345 = 432 \text{ meters per second.}$$

Masson gives 401 meters per second as the velocity in water vapor at 0°C. Although no factor for temperature correction is available it seems that Masson's value is considerably below the value given above. Failure to provide air-free vapor for the determination would account for the low value. Since the effect of air in the vapor is to decrease the velocity, the largest value one can obtain for the velocity would presumably be most reliable.

With the value for the ratio of specific heats and density of water vapor given by Neyreneuf³ we get a theoretical value for the velocity of sound in water vapor at 27°C which is $V = 348(1.321/0.6143 \times 1.402)^{1/2} = 431$ meters per second. Neyreneuf's data were given for saturated vapor, whereas, the vapor pressure used in the present experiments was only slightly more than half that of saturated vapor. On the whole, the agreement is quite satisfactory, considering the errors involved in the measurement of the various quantities.

UNRELIABILITY OF PHOTOGRAPHIC EMULSIONS ON GLASS
FOR RECORDING DISTANCES AND A METHOD
OF MINIMIZING THIS DEFECTBy D. COOKSEY AND C. D. COOKSEY
SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received May 19, 1930)

ABSTRACT

Superficial motions of double coated emulsions were investigated by Schlesinger's ink dot method. Also the positions of developed images with respect to corresponding latent images were studied for singly coated plates. Apparently *there are stresses in undeveloped gelatin emulsions that can be relieved* before plates are used for photographic purposes by soaking them in water followed by dehydration in alcohol, *thus greatly enhancing their reliability for recording distances*. This process we have termed *normalizing*. The maximum observed change in a distance between images, in their latent and developed states on a singly coated plate was 9μ without normalizing and 2.2μ with normalizing. The average change was likewise reduced to about one quarter. The advantage of normalizing is emphasized by the results reported in another paper.

MUCH effort has been expended in determining what reliance may be placed on photographic emulsions when used for recording the relative positions of star images and spectral lines. Many things affect the answer to this question. A very complete account of this subject, with bibliography, has been given by F. E. Ross.¹ Some years ago Professor Frank Schlesinger,² and recently E. Bäcklin,³ reached the conclusion that the position of a latent image is not appreciably altered in the processes of development. Schlesinger used a method of investigation in which artificial star images were produced on a photographic plate by spattering it with water-proof india ink. This plate was subjected to the ordinary developing, fixing and washing processes, except that the developing agent was omitted from the developer. The coordinates of a large number of ink dots were accurately determined before and after development. He reached the conclusion that any error due to distortion of the gelatin was negligible in comparison with the errors of measurement, and has since informed us that a subsequent unpublished investigation has led to the same conclusion.

During our work on the development of the "method of displacement" for measuring x-ray glancing-angles, we built and tested a specially designed spectrometer.⁴ The mechanical errors in this instrument and also the errors of manipulation were so small that they were negligible compared to the errors of measurement of distances between spectral images on photographic

⁴ C. D. Cooksey and D. Cooksey, following paper. This issue.

plates. As this method is based partly on the assumption that the emulsion surfaces are plane and parallel, we decided to obtain plates more suitable for this purpose than those sold commercially. Through the kindness of Dr. C. E. K. Mees, the Research Laboratories of the Eastman Kodak Co. furnished us with "parallel plate" glass coated with a double thickness of x-ray emulsion. Several spectrograms of the $K\alpha_1$ line of silver were taken on these plates. Corresponding distances between images, which should have been constant to less than one micron, were found to differ between plates by as much as ten microns, a difference altogether too large to be accounted for by instrumental errors or those of measurement. In consequence, we were forced to suspect the constancy with which the position of a latent image is retained by its developed image, at least in the case of these double coated plates.

To investigate this, we adopted a modification of Professor Schlesinger's method. Plates were cut in strips 25 cm long and 3.4 cm wide (the size used for spectrograms) and spattered with water-proof india ink along their longer center-lines. The distances between ink dots were measured on a carefully calibrated Gaertner measuring engine, which is fully discussed in another paper.⁴ The errors of the screw, bearings and divided head were eliminated by always using exactly the same portion of the screw for the remeasurement of a given distance. The screw coördinate of each edge of each selected ink dot was determined three times. From the mean of these three determinations the distance between dot centers was obtained. The plates were measured before and after they were subjected to various soakings, dryings and development. The so-called developer used contained sodium sulphite, sodium carbonate and potassium bromide in the usual proportions, but no developing agent. The fixing bath contained sodium thiosulphate, sodium sulphite and acetic acid, but no alum or other hardener.

Preliminary investigations showed, as others had previously found, that the reliability of the gelatin was very dependent on the method of drying after development and washing. The essential factor in drying is that it shall take place uniformly. This condition is approached when the water is displaced from the gelatin by immersing the plate in strong ethyl alcohol; but as the alcohol will displace more water than is normally contained in the gelatin, the plate, if exposed to dry air, will become cloudy as the alcohol evaporates. This may be completely overcome by evaporating the alcohol in a humid atmosphere such as that in a box lined with wet blotting paper. As this part of the work was done in the summer, when the humidity is high, it was unnecessary to take this precaution. Furthermore we were led to believe that there were superficial longitudinal stresses in this gelatin, introduced while the emulsion was cooling during the process of manufacture. In order to relieve these stresses, plates were soaked in water for thirty minutes, dried in alcohol for twenty minutes and finally left to attain equilibrium in a humid atmosphere. This process, as applied to fresh plates, we have termed *normalizing*.

The accuracy of the measurements can be estimated from the following

data. The average variation of one setting from the mean of three settings on a given dot edge, obtained from 282 settings on 39 ink dots, was 0.19μ before, and 0.14μ after development, with a maximum variation from the mean of 0.7μ and 0.6μ respectively. The difference in accuracy is due to the difference in illumination before and after the silver salts had been removed. Eighteen distances on a developed plate, varying from 0.01 to 60 mm in length, were remeasured according to the above procedure on three different days during the course of a week. The average of the differences of these three determinations from their means was 0.09μ with a maximum variation of 0.3μ . Table I gives changes observed in distances between ink dots on a series of seven plates, measured before and after the plates were subjected to the treatments specified.

TABLE I. Comparison of changes in distance between ink dots on double coated plates resulting from various treatments.

measurement	Treatment before remeasurement ¹	No. of distances	Maximum change, μ	Average change, μ
None	developed and dried without alcohol	3	3.7	2.5
None	any wetting process and dried with alcohol	3	4.1	1.8
Wetted and dried with alcohol	wetted and dried with alcohol again	45	0.8	0.32
None	normalized	22	4.9	1.35
Normalized	developed and dried with alcohol	36	0.8	0.3

(By "developed" is meant 5 minutes and 20 minutes respectively in the developer and fixing bath described above, and 30 minutes in running water.)

These results seem to indicate that normalizing relieved stresses, thereby reducing the average relative displacements on development to about one-fifth. They lead to no conclusions as to the motions that may occur at the glass-gelatin surface or in intermediate layers. In connection with these results, Dr. Mees pointed out that certain precautions used in the manufacture of commercial plates were omitted by the Research Laboratory in preparing these double coated plates for our use.

In order to determine the reliability of the position of a developed image with respect to that of its latent image, the work was continued as follows. We constructed a template, about 78 mm long and 17 mm thick, of steel with ends lapped plane and parallel. Two parallel slits at a fixed distance apart were formed by bolting similarly prepared blocks to the ends of the template, the width of opening of the slits being adjusted to less than 0.02 mm by shims. By allowing x-rays to pass through the slits onto a photographic plate clamped to the template, very sharp-edged lines were obtained. Thirteen strips 3.4 cm wide were cut parallel to the 5 inch side of four 5×7 Eastman Universal plates taken from the same box. The emulsion of these plates is about 0.025 mm thick. The template, or rather the slits which terminated it, was photographed with x-rays approximately centered on ten of these strips. All thirteen strips were then normalized and the template rephoto-

graphed on nine of the strips, including, of course, some of those already bearing latent images. The strips were finally all developed in "Eastman X-ray Developer," fixed and washed. After washing they were soaked in strong alcohol for about 10 minutes and then dried in a humid atmosphere. The results of the measurements on the developed images are given in Table II.

TABLE II. *Comparison of reliability of normalized and unnormalized singly coated plates.*

	Unnormalized	Normalized
Number of distances measured	10	9
Maximum difference in lengths measured	9.0 μ	2.2 μ
Average difference from the mean	2.8 μ	0.7 μ
Probable error of one determination	$\pm 2.2\mu$	$\pm 0.5\mu$

As all these plates were handled in the same manner and subject to the same uncertainties of measurement, it is obvious that the *reliability of a photographic plate as a recorder of definite distances is greatly enhanced by the normalizing process*. However, by taking proper precautions during the process of manufacture, it might be possible to avoid the introduction of these stresses here relieved by normalizing. The fact that local stresses, due to non-homogeneity or other causes, may exist in gelatin, and do cause shifts of images by as much as 2μ is thoroughly treated by Ross. However, he states that 2μ is the maximum shift to be expected. We wish to call particular attention to the fact that we have found occasional motions as large as 9μ which occurred due to the relief of stresses existing in singly-coated commercial plates, and that if such stresses are not relieved before such a plate is used, it will not be reliable for positional recording. It would therefore seem to us advisable to subject plates to a normalizing process when they are intended for use in recording unique occurrences, such as eclipses, if intervals between images are of prime importance. Even when images may be recorded on many plates, given that the resulting definition permits of measurement to less than 2μ , normalizing will increase the self-consistency of measurements between plates in proportion to the accuracy of the individual measurements, as long as other causes of variation do not enter, such as pressure shifts of spectral lines, etc. This statement is, we hope, clearly verified by Table XI of another paper.⁴ It might not be amiss here to emphasize a point clearly demonstrated by Ross (page 197)¹ but contrary to what has been commonly assumed as an excuse for variations of measurements; viz., the non-uniformity of image contours. Our experience, in common with Ross's, is that well filled, sharply outlined images are just as liable to a shift as their "moth-eaten" relatives.

The particular object of this investigation was to determine a reliable method of handling spectrograms of sensibly the same dimensions as used by us in determining glancing-angles. During the course of the work we made certain observations which we did not feel called upon to verify because the normalizing process and subsequent drying with alcohol proved satisfactory for our purpose. However, we shall suggest conclusions which may be drawn

from them in the hope that they may be of interest. The edge-effects referred to by Ross and others have been reproduced by us, both with ink dots and developed images. The motions referred to in our tables are not due to edge effects, but frequently occur in the central region of the strips within a length of two or three millimeters. We found that we could control at will the direction of motion of an image by removing a strip of gelatin parallel to the image and at a distance of one centimeter or less from it. The evidence thus obtained, although not conclusive, indicated a compound effect made up of two independent causes; one, the diffusion of silver grains away from the drying edge* ("hydration gradient," cf. Ross), and the other, a contraction of the gelatin causing a bodily shift of the matrix toward the dried edge. It is believed that the former of these causes might readily change the scale of a photograph, in the region drying last, when alcohol is not used for dehydration.

We have been informed that gelatin, with or without the silver halides, normally contains about 15% water. One attempt was made to do away with the necessity of evaporating in a humid atmosphere by using about 75% alcohol. The resulting plate was free from clouding, but large stresses persisted in the gelatin. We therefore were content with the successful technique which employed the use of ethyl alcohol, at least 90% pure, and evaporation in a humid atmosphere. As the surface tension of alcohol is low, dirt specks adhere to the gelatin. Consequently all dust particles should be removed before the plate is placed in the alcohol, which in turn must be dust free. Although the plates used were soaked face up, we would suggest immersing them horizontally face down. If a plate is immersed standing in an approximately vertical plane, the gelatin will dry with ridges across its surface as though the displaced water had flowed down in tiny rivulets. The alcohol was evaporated with the plates in a plane making 45° with the horizontal, gelatin side up, and resting diagonally on one corner. However, we found no evidence to show that the drying position made any difference on alcohol soaked plates.

In conclusion we wish to express our indebtedness to Professor Frank Schlesinger and to the late Professor B. B. Boltwood for helpful suggestions in connection with this investigation. We are also indebted to Professors McKeehan and Uhler for advice in connection with the presentation of this work.

* Dr. Mees informed us that silver grains would diffuse into the region more highly saturated with water.

PRECISION MEASUREMENTS OF THE GLANCING-ANGLE OF REFLECTION FROM CALCITE FOR SILVER ($K\alpha_1$) X-RAYS BY THE "METHOD OF DISPLACEMENT."¹

BY C. D. COOKSEY AND D. COOKSEY
SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

ABSTRACT

Part I. Method of displacement.—This method permits the determination of glancing-angles in terms of *linear measurements only*. It consists in letting a properly limited beam of x-rays, after reflection, fall on a photographic plate placed successively in two parallel positions which differ in distance from the crystal by a known amount. The theory of the method and its practical application to the present case are briefly discussed with references to Uhler's paper.

Part II. Apparatus and Adjustments.—A new high precision spectrometer, including a specially designed bearing on which the crystal rotates and a unique form of plate holder using air pressure to ensure the flatness of the photographic plate, is fully described. A *special* form of hot filament *cathode* which gives an approximately *linear source* of x-rays has been originated. Precision methods for adjusting and testing the reliability of the instrument are discussed at length. It is believed that the instrument is free from any defects that might cause a constant error of as much as 0.04" in the glancing-angle.

Part III. Experimental procedure.—The cleavage planes of a nearly perfect specimen of Iceland spar were used as grating. The bearing of its perfection on the widths of the spectral images is discussed. *The coefficient of expansion of calcite* normal to the cleavage planes was computed from the most reliable data obtainable. A mean value which is sufficiently precise, over a sixteen degree range, to reduce values of glancing-angles to 18°C within 0.008" is $1.02_3(10)^{-5}$ per °C. Attention is called to the fact that the commonly used value $1.04(10)^{-5}$ is not a sufficient approximation.

Distances between spectral images on each negative were measured on a Gaertner measuring engine, the errors of which were carefully investigated. The "displacements" of the photographic plate were equal to fixed intervals marked on a measuring bar and calibrated against the screw of the same measuring engine. The accuracy of these measurements and the effect of their errors on the glancing-angle are discussed.

The experimental procedure and precautions used in taking and measuring spectrograms are fully described. A complete protocol of observations is given for one plate. Evidence for the accuracy of the measurements is presented and discussed.

Part IV. Results.—The weighted mean value of the glancing-angle for the $K\alpha_1$ -line of silver from the cleavage planes of calcite at 18°C is $5^\circ 17' 13.81'' \pm 0.06''$ giving a wave-length, if $\log 2d_{18} = 0.7823350$, of 0.558238Å. This result is compared with those of other observers. It differs from Kellström's value quoted by the Int. Crit. Tables by more than ten times the combined probable errors. The only probable source of an adequate constant error in either result seems to lie in the crystal. Compton's measurements of the density of calcite are invoked to prove that different specimens of Iceland spar do differ enough in density to account for more than the discrepancy, if changes in density and grating space are interdependent.

¹ The final numerical results published in this paper have already been given by us in a letter to the Phys. Rev. [2] 35, 564 (1930) and Nature 125, 461 (1930).

PART I. THEORY OF THE METHOD OF DISPLACEMENT

VERY precise methods have been developed for measuring the glancing-angles at which characteristic x-rays are reflected by a crystal. In most cases where the highest precision has been attained, the results are based on measurements with a divided circle. In 1917 H. S. Uhler,² of this laboratory, suggested the so-called "Method of Displacement," by which glancing-angles are computed from linear measurements only. The method was given a preliminary trial, at the time, by Uhler and one of us³ and gave results of greater accuracy than any hitherto reported. The present work was undertaken for the purpose of developing this method to the high degree of precision of which it seemed capable. Unforeseen difficulties delayed the work until divided circle methods had been developed to give a precision that we could not expect to surpass. However, glancing-angles are of such importance that, it seemed to us, their values should be checked by an independent method of equal reliability, and therefore the work was continued.

The method is a photographic one and "consists in taking one exposure when the plate is at a certain distance from the crystal and then a second exposure when it is at a different distance from the reflector. The displacement of the spectral image, corresponding to some one wave-length, is a function of the distance through which the plate has been *translated* parallel to the collimation line. The form of the function and the details of the calculation of the glancing-angle depend respectively upon the value of the constant angle between the normal to the plate and the collimation line, and upon whether the measurements are absolute or are based upon adjacent images pertaining to known wave-lengths. The interval of translation may be determined with ease and great accuracy, whereas only an approximate value of the distance between the plate and the axis of rotation is required in any case."² It involves the fundamental assumption that the plate, in each of its chosen positions, intersects a region of the reflected beam in which the intensity is symmetrically distributed about a line which makes an angle with the axis of the incident beam equal to twice the glancing-angle. Such a region can be obtained approximately, in the case of a *perfectly selective* reflector, if the incident beam completely fills, and is limited by, two narrow slits whose long axes are parallel to the axis of rotation of the reflector; provided that the aperture of the beam in the plane of the long axes of the slits is sufficiently limited. The region then lies between the Bragg foci of the two slits. The condition that the reflector be *perfectly selective* is not fulfilled by real crystals, but it will be shown later that the crystal used in the present work reflected a beam of the required symmetry.

The function by which the glancing-angle can be computed from the measured data is easily derived from the geometry of Fig. 1. This figure is drawn in a plane which is perpendicular to the mutually parallel long axes of slits S_1 and S_2 , axis of rotation and reflecting planes of the crystal. For simplicity the axis of rotation is assumed to intersect the line of centers of

² H. S. Uhler, Phys. Rev. [2] 11, 1 (1918).

³ H. S. Uhler and C. D. Cooksey, Phys. Rev. [2] 10, 645 (1917).

the slits and to lie in the mean reflecting plane of the crystal, but the final result is independent of these assumptions. O is the point of intersection of the axis of rotation with the axis of the incident beam XX' . ORR' and OLL' represent reflected rays on either side of the direct beam and inclined to it at twice the Bragg angle of reflection, θ . LR and $L'R'$ are the parallel traces of the photographic plate in its two positions and intersecting the reflected rays at the points L, R and L', R' between the Bragg foci of the slits. The central ray, XX' , intersects the plate at the points C and C' and makes the angle ω with the normal to the plate, OPP' . The dotted lines LL'' and RR'' are drawn parallel to XX' .

Fig. 1. Geometry of the "Method of Displacement."

If $x \equiv R'R''$, $y \equiv L'L''$, and $D \equiv CC'$, the angles θ and ω are given by

$$\tan 2\theta = \frac{2xy}{D(x+y)} \left[1 - \frac{D^2(y-x)^2}{4x^2y^2} \right]^{1/2} \quad (1)$$

$$\sin \omega = \frac{D(y-x)}{2xy} \quad (2)$$

If the plate is translated in the direction XX' , the quantities x and y are respectively equal to the distances between corresponding spectral images on each side of the image of the direct beam, and D is the distance the plate has been displaced. But if the direction of translation is inclined to XX' , the images of the undeviated beam taken in the two positions of the plate will not be superposed, and their separation must be measured and used in computing x and y from the separation of the spectral images. It is not difficult, in practice, to make this inclination so small that D may be taken as the distance the plate has been displaced in its line of motion without sensible error, but a corrected value of D can always be computed from this distance and the separation of the central images.

The quantity within the brackets in Eq. (1) is $\cos^2 \omega$, and therefore this term has very little effect on the value of θ , if ω is small. For small values of ω , the effect of this factor will be a maximum for glancing angles in the

neighborhood of $22^\circ 5'$. Even if ω is as great as $3.5'$, the omission of $\cos^2 \omega$ only causes an error of $0.03''$ at such glancing-angles, and at 5° , the region under investigation, the error is only $0.01''$. When $\cos \omega$ and the central image displacement can both be neglected, the glancing-angle may be computed with sufficient accuracy from

$$\tan 2\theta = \frac{L'R' - LR}{2D}. \quad (3)$$

Thus the result depends on the measurement of intervals— LR and $L'R'$ —each of which separates spectral images taken with the plate in a single position. This is an advantage if the spectral images corresponding to different positions of the plate have not the same width, and it is desired to use parallel hairs in the eye-piece of the measuring microscope.

A very full discussion of the geometry of image formation as applied to plane space-gratings, treated as perfectly selective reflectors, is to be found in Uhler's paper.² We therefore omit a detailed consideration of the effects of extreme rays and of inaccuracies in adjustment, and will merely cite these effects and the precautions taken to eliminate them in a later part of this paper.

PART II. APPARATUS AND ADJUSTMENTS

The work was begun on an apparatus, designed by one of us,⁴ but the results obtained lacked the accuracy of which the method was capable. Investigation showed the following defects: the apparatus as a whole was not sufficiently rigid; the plate-holder did not make the photographic plate flat and could not be displaced without fortuitous rotations; various parts of the apparatus were subject to distortion by small changes of temperature; and the axis about which the crystal rotated was indefinite. It was decided to build a new spectrometer which would be subject in use to no distortions causing a motion of one part relative to another of as much as 0.25μ . We are deeply indebted to Mr. Paul M. Mueller, then in charge of the Gauge Department of the Pratt and Whitney Machine Tool Co. of Hartford, Conn., for the design of a new spectrometer and plate-holder, which were built by that company under his constant supervision. The bearing for rotating the crystal was designed by him, and the unique form of plate-holder finally adopted was his original idea. We are also grateful to the Pratt and Whitney Co. for their very careful construction of the instrument.

Fig. 2 shows a view of the essential parts of the apparatus as set up for taking spectrograms. It is a tracing made from a photograph, and the wooden measuring stick, one-half meter long and divided in centimeters, fastened to base A, shows the scale in one direction. The radius of the divided circle table L is 13 cm, and the webbing of the castings varies in thickness from 1 to 1.5 cm. The whole assemblage weighs about 200 kg and rests on a stone-topped brick pier.

The primary base A is a standard Pratt and Whitney measuring engine bed, made of cast iron and aged by exposure to the weather for several years,

⁴ C. D. Cooksey, *Phys. Rev.* [2] **16**, 305 (1920).

after having been machined. The maximum vertical depth of the casting is 25 cm. The upper surface is 146 cm long and consists of two parallel ways or rails separated by a *T*-slot. The farther way is flat; the nearer is, in cross-section, an inverted 90° "V", truncated. After strains had been relieved by aging, the ways were scraped straight to conform to a "master." This base is supported on three leveling screws, furnished with lock nuts, one of which is near the forward end and directly under the center line between the ways. The bracket *M* which carries the forward slit S_1 fits the track and, when in use, is locked directly over this foot.

Fig. 2. Spectrometer assemblage.

The secondary base *B* is an iron casting in the form of an "I" beam, reinforced with heavy vertical cross webs. It is 56 cm long, 11.5 cm wide at top and bottom, and 16.5 cm high. The bottom surface was machined and scraped to fit the rails of base *A* accurately, so that *B* may be considered an integral part of *A* when locked in place. Thus, any bending stress due to a load on *B* will be resisted by a section of cast iron 41.5 cm deep. The position of *B* relative to *A* may be adjusted and fixed by means of the screw and clamp shown at the left of *B*. The upper surface of *B* consists of a track, a vertical cross-section of which is shown in Fig. 3.* The straightness and rigid-

Fig. 3. Cross-section of ways on base *B*.

* Ways of this type were chosen because they have a vertical axis of symmetry and therefore permit the reversal of the "master" during the process of scraping the ways straight.

ity of these ways are essential to the success of the displacement method, as it is along them that the plate-holder carriage is moved. The scraping of the bearing surfaces of this track was done with extreme care. When assembled the track on *B* is very nearly parallel to that on *A*.

The plate-holder carriage *F* (the forward end of which is also shown in Fig. 4) rests on the track on *B*. It has bearing surfaces 15.5 cm long which were scraped to fit this track with great accuracy. It is provided with a slow motion adjusting screw *I*, and may be locked in position by a clamp operated by a level seen just to the right of the letter *F*. A portion of its upper surface was scraped flat and in the assemblage is parallel to the upper surfaces of the track on *B*, and serves as a seat for the measuring bar *H*. The forward end of the carriage is a vertical "goose-neck" having a horizontal hardened steel plate bolted to it. This plate has a "V" groove milled across its upper surface and serves as a support for the plate-holder *J*. The carriage with the bar and plate-holder weighs 15.1 kg.

H is a standard 12 in. Pratt and Whitney steel measuring bar, adapted for our use. The lower and back surfaces are scraped flat. In the front surface are thirteen hardened steel plugs with their outer ends ground and polished so that their surfaces lie all in one plane, parallel to the opposite surface of the bar. The plugs are numbered from left to right, beginning with zero and each has a very fine line, ruled with a diamond. The lines are accurately parallel and are approximately perpendicular to the lower surface of the bar. The distances between successive rulings are very accurately 1 "U. S. inch" each. The bar is held in place on the carriage by a tapered dowel pin which fits in a reamed hole at the left end of the bar. Two horizontal set screws (one of which is shown at *V* in Fig. 4) near the right hand end of the bar bear against a stud in the carriage which passes through an oversized hole in the bar. This permits the adjustment of the plane of the ruled plug surfaces parallel to the line of motion of the carriage.

The axis marked *XX'* in Figs. 1, 2, and 4 is defined as a line parallel to the line of motion of *F* and intersecting *Y*, the axis of rotation of the crystal, at the fixed elevation of the center of the slit *S*₂.

The microscope bracket *D* clamps to a short hollow cylinder which is bolted to a scraped surface on the central web of base *B*. The microscope is clamped in an eccentric collar *E* in the upper end of the bracket, and can be adjusted to any desired position. It is of 75-power and has a micrometer eye-piece. The movable reference lines ("crosshairs") are two fine diamond rulings on a glass plate and intersect at an angle of one radian. When the microscope is in proper adjustment the bisector of this angle is parallel to the vertical fiducial lines on the plugs of the measuring bar. An axial illuminator can be mounted on the forward end of the objective housing.

The bearing mechanism for rotating the crystal, and the slit *S*₂, are supported on a base which somewhat resembles a sled, the two runners of which embrace the lower edges of the base *B*. The nearer of these runners is shown in Fig. 2 and is labeled *C*. This base can rotate about an accurately fitting horizontal trunion bolt which passes transversely through the runners and *B*.

The lock nut and washers of the nearer end of this trunion are partly visible behind the wheel *K*. The base is adjusted and locked in position by means of two set screws in the left hand end of each runner; they bear against studs screwed into *B* through oversized holes in the runners. This mounting is thus a sort of cantilever and permits a necessary adjustment of the axis of rotation of the crystal with respect to the rest of the instrument.

Two vertical posts, one of which is shown, bolt to the forward end of the sled and have bolted to their upper ends a steel cross piece *N*, which in turn carries the adjustable mounting for the slit *S*₂. In the center of the sled is a scraped seat, with a large hole bored through it, to which is bolted the bearing for rotating the crystal.

The parts *B*, *C*, *D*, *F*, *J*, and *M* are made of cast iron. After being machined, but before the final finishing was done, they were artificially aged. The aging process was apparently effective, for none of the parts has shown any noticeable warping during several years.

A section of the plate-holder *J* in a plane parallel to that of *XY* is shown at (a) in Fig. 4 in position on the carriage *F*, and in perspective with the cover partly removed at (b). The holder is supported and positioned by two cone-pointed bolts, one of which is shown at *T*, and the round-ended screw *U*. The cone points fit in the slot milled across the steel plate which is bolted to *F*, and the screw *U* bears against a plane surface milled on *F*. The cone of one of the bolts is not coaxial with the bolt, thus permitting a small rotation of the plate-holder about a vertical axis. Adjustment about the line of the slot is made with the screw *U*. The center of gravity of the plate-holder is far enough forward of the screws *T* to keep the holder in position when the carriage is moved. The plate-holder is so compact that the distance from the center of the plate to the surface of the track below is only about 5.5 cm.

The plate-holder is of special design to ensure the flatness of the sensitized surface of the photographic plate. This surface is forced against two parallel flat surfaces on the cover, just to the left of *OO*, by thin walled rubber tubes *RR'* inflated with air at about two atmospheres pressure. The two surfaces *OO* are an integral part of a sufficiently large body of cast iron to prevent bending under this stress.

The cover of the plate-holder is one casting in the form of two *V*-sections joined together at both ends; these are reenforced by seven cross webs on each side, which terminate in bosses through which the fourteen screws *QQ* hold the cover to the back. Each of the *V*-sections is of the nature of a cantilever, such that the pressure on the surfaces *OO* causes a tension in the screws *QQ* and a pressure across the surfaces of contact between the cover and back of the plate-holder at *PP*. The back of the plate-holder offers about five centimeters depth of cast iron to resist both these stresses. The opposing surfaces of the cover and back, as well as the surfaces *OO*, were scraped plane to a high degree of precision. It had been the original intention of the designer to finish these surfaces by lapping, but it was feared that the slight peening action of the abrasive would only warp them. The edges of the sur-

faces were left sharp so that in working the two parts of the holder into contact dust particles would be removed.

Fig. 4. Cross-section and perspective of plate-holder.

A strip of black paper, fitted into slots in the V-sections, covers the opening between the sections and serves as a light seal. A centimeter scale, ruled on the surface *S* along one side of the opening, facilitates the positioning of a lead screen when it is desired to shield a portion of the plate from x-rays. The photographic plates were cut in strips 25 cm long and 3.4 cm wide, dimensions such that the extreme edges of the strips extended slightly beyond the boundaries of the surfaces *OO*. This was to prevent irregularities in the edges of the gelatin from interfering with the proper seating of the plate.

The mahogany strip *W*, backed by a piece of velvet, and having two longitudinal grooves 6 mm wide milled in its front, affords support for the rubber tubes and distributes the pressure in them uniformly to the back of the plate-holder. The portions of the rubber tubes which press against the photographic plate are thinner than the remainder. We are indebted to Mr. G. W. Patterson of the Seamless Rubber Co. of this city for these tubes. Air is admitted to the tubes through a nozzle shown just below the letter *J*, Fig. 2. The tube *R'* is shown inflated in the section. When the tubes are deflated. There is ample clearance between the plate and the surfaces *OO* to prevent scratching of the gelatin while the cover is being worked into place. The plate-holder assemblage weighs 5.6 kg.

Fig. 5. Cone bearing.

The cone bearing for rotating the crystal is shown in Fig. 5. The flange on the seasoned cast iron sleeve *B* was scraped to fit its supporting seat on base *C*, Fig. 2, and the sleeve passes through the hole in this seat. The steel spindle *A* is a right circular cone supported by a hardened steel foot *C*; the lower surface of *C* is spherical and rests on the upper plane surface of *D*, also of hardened steel. The lower part of *D* is a stud which fits tightly in the sleeve *F*, and the latter has a sliding fit in *B* and a long enough bearing to keep *D* from rocking. The stud rests on the screw cap *E*, which is threaded to *B* with a fine thread and serves to adjust the bearing. By using a long tommy in the holes provided in *E*, the spindle and all its superstructure can easily be raised by as little as 2.5μ at a time. As the tangent of the semi-apical angle of the cone is slightly less than 0.06, an accurate means is at hand for adjusting the oil film separating the surfaces of *A* and *B* to the minimum thickness required for

lubrication. If this adjustment was correctly made at one angular position of the cone, it was found to be correct for all others, showing that the cone and its bearing fitted accurately. This corroborated what had already been inferred from the usual test with prussian blue. When the spindle was properly adjusted, a diminution in the thickness of the oil film of 0.3μ would cause the oil to cease acting as a lubricant. Therefore the cone may be considered to rotate in B about a practically *fixed* axis.

An essential feature of the design of the sleeve B is that portions of its bearing surfaces are relieved to insure the proper distribution of the oil and to prevent particles of foreign matter from getting between the bearing surfaces. This is done by removing one half the bearing area of B by three grooves, similar to rifling, but running parallel to the elements of the cone. The edges of these grooves were left sharp. This bearing was originally set up four years ago with "3 in 1" oil for lubricant, and the above tests and adjustment made. Since that time, no oil has been added, nor has any adjustment been found necessary by later tests. The oil shows no sign of having evaporated, or of becoming sticky after lying idle for six months at a stretch. It is doubtful if expensive watch oil would have been more satisfactory. If such a bearing was being built for continuous use, it would be well to replace the steel bearing surface of D by one of agate.

The spindle A is bolted to the divided circle table L , Fig. 2, and can be rotated by a tangent screw, the divided head of which appears at K in the figure. Screwed to the upper surface of this table and coaxial with it, is a circular brass plate with three radial slots 120° apart which serve to position the crystal holder or an auxiliary slit.

The bilateral slits, S_1 and S_2 , have gold jaws 2.4 mm thick, 2.5 mm wide, and 1 cm high, inserted in brass plates which slide in dovetails on the slit frames. The opposing surfaces of the jaws were carefully scraped flat. The slit widths can be varied by means of cams acting above their centers; but during the taking of spectrograms one jaw of each slit is held in place by two dowel pins, and the other jaw is clamped tight against platinum shims placed between the opposing surfaces above and below the limited portion of the slit used. The slit S_2 is at a fixed height above the supporting bar N , but S_1 can be raised or lowered. Both slits can be rotated about horizontal axes through their centers and about vertical axes, and can be translated at right angles to the plane XY .

The crystal holder assemblage is shown mounted on the table L . Its base is a brass disk with three cone feet which fit the slots provided for it. On this base is mounted a rectangular plate with lateral adjustment. The plate supports, in a vertical sleeve with locking set screw, a sliding post which carries at its upper end the outer of a pair of coaxial cylinders. The inner cylinder can be rotated with respect to the outer by a tangent screw. The crystal is fixed by soft wax with its working face against the surface of a slotted brass plate, which bolts inside the inner cylinder in such a manner that the axis of the latter lies approximately in the face of the crystal. Thus, the lateral and rotational adjustments of the crystal are independent. The

crystal holder can be replaced by an auxiliary slit (not shown) later referred to as S_3 . The latter is so adjusted that, when in place, its long axis coincides with the axis of rotation Y , and the plane through its upper corners contains the axis XX' .

The x-ray tube is mounted on a bakelite stand in a rectangular box of 5 mm lead sheet. The box is supported on two pieces of channel steel 31 cm deep which rest on the same pier as the spectrometer. The tube used in these experiments was entirely constructed in this laboratory and was of Coolidge type with 15 cm bulb. The target was a button of silver welded, to insure good thermal contact, to a water-cooled copper anode. The x-rays were taken at an angle of about 3.5° to the plane of the target. The cathode, heated by current from a storage battery, was designed to bring the cathode rays to an approximately line focus on the target. With this in view, the filament was wound in a spiral groove on a tapered mandrel, just as for a fine focus Coolidge filament; but, instead of being annealed between spherical surfaces, it was placed between cylindrical surfaces of 19 mm radius during annealing. This gave a focal spot on the target which was longer in one direction than in a direction at right angles; but, due to the magnetic field of the heating current, its long axis was inclined at an angle (roughly 45°) to the axis of the cylindrical filament. This is a drawback if it is desired to change the strength of the filament current after the tube has once been aligned with respect to the spectrometer. We hope to overcome this difficulty by the use of a non-inductive filament. Such a filament should have a greater thermionic emission at its center, owing to the elimination of the center lead, and should give an excellent focal spot distribution. We have succeeded in winding such a double filament, but have not had an opportunity to mount and try it.

The cooling water was circulated by a pump through a Ford automobile radiator and its temperature measured just before and just after passing through the anode. By regulating the speed of a fan blowing on the radiator, the temperature, and therefore the length of the anode could be held constant, thus keeping the focal spot on the line through the narrow slits used.

The source of potential for the tube was a 10 K.V.A. transformer connected to the 220 volt, 60 cycle, city supply. It was controlled by a variable inductive reactance in the primary and had a mechanical rectifier in the secondary, utilizing about one half of each side of the wave.

For precision measurements with the above described apparatus, it is essential that the plate-holder, when the carriage F is moved along its ways, should have rectilinear motion only; and that there should be no appreciable motion of the microscope relative to the crystal. It is also important to have the planes of the opposing faces of the slit jaws parallel to the plane XY , and the reflecting planes of the crystal approximately parallel to the axis of rotation. These adjustments were made with the aid of several steel mirrors of different thickness, each having two opposite reflecting surfaces accurately plane and parallel; and an auto-collimating device for detecting and measuring any rotation of the mirrors. The auto-collimator consisted of a 43 cm focal length objective with illuminated cross-hairs in its focal plane. The

90° cross-hairs, together with their reflected image, were viewed with a 20-power micrometer microscope. The sensitivity of this arrangement was 7, micrometer divisions per second of rotation of the mirror, and one-third of this rotation could be detected. For detecting small motions of one part of the spectrometer relative to another, two steel balls were fastened to one part, a third ball to another, and on a glass or hardened steel plate resting on these three balls was mounted a mirror facing the auto-collimator. When the balls bore on hardened surfaces, scrupulously clean, a relative motion of 0.01μ could be detected by this device.

Making use of this tilting mirror, it was found that the largest relative motion between the spectrometer microscope and the axis Y , due to moving the carriage F with the plate-holder along the ways, was the entirely negligible amount of 0.06μ . The carriage, when displaced the full length of the ways, rotated about horizontal and vertical axes perpendicular to its line of motion by the insignificant amounts of one and two seconds respectively, as measured with the auto-collimator. A sensitive spirit level showed no greater rotation about its line of motion.

These tests having been made, the sled C was adjusted, with the aid of the auto-collimator and mirrors until the Y -axis was perpendicular to XX' . A micrometer microscope, giving 45° deviation, was then clamped to the carriage F and adjusted until the axis of its objective coincided with the line XX' , thus supplying a means for bringing the centers of the slits S_1 and S_2 into this line.

The measuring bar was adjusted by a dial indicator until the scraped surface on the side opposite the plugs was parallel to XX' to within 3 seconds of arc. Since the surfaces of the plugs had all been ground and polished into one plane parallel to this scraped surface, this adjustment brought their surfaces parallel to XX' , and insured all of the diamond scratches being in focus without parallax as they came opposite the microscope, once this was focused on one of them.

By means of a mirror wrung to the vertical scraped surface of H , another on the divided circle table with its surfaces parallel to the axis Y , and mirrors clamped between the jaws of the slits S_1 and S_2 , the auto-collimator could be set with its axis normal to the plane XY , and the slits adjusted until the surfaces of their mirrors were parallel to this plane. The slit surfaces were thus adjusted parallel to Y within 30" and to XX' within 15". In a similar manner the plate-holder was adjusted so that the plane of the photographic plate would be approximately perpendicular to the axis XX' . The crystal, which had a cleavage face giving fair optical reflection, was similarly adjusted so that this face was parallel to the axis Y and as nearly as possible in this axis, the latter adjustment being made with a high power microscope. The various mirrors were brought opposite the auto-collimator by sliding the carriage B , and slit bracket M along the tracks on A . Wherever possible, the foregoing tests were checked with a spirit level sensitive to 5 seconds of arc per mm displacement of the bubble and, in some cases, with one of five times this sensitivity.

The greatest care was used to test the flatness of the opposing surfaces of the two parts of the plate-holder, not only when the plate-holder was disassembled and free from stress, but also when it was assembled and the air pressure applied.

The front portion, mounted on the carriage *F* in such a manner that it could be moved parallel to the surfaces *OO*, was examined with an interferometer using parallel and approximately monochromatic green light. The high portions of the scraping marks on these surfaces were so nearly continuous, and so well polished from working the two parts of the plate-holder together during assemblage, that the fringes were entirely unambiguous and could be counted. After allowing for the slight departure of the motion of *F* from a straight line, the surfaces *OO* were found to be flat to one fringe.*

The back of the plate-holder was similarly mounted on the carriage *F*, but the scraping marks were not close enough together to give useful fringes. However, with mirrors wrung to its surfaces in various places, it was tested both with the interferometer and the auto-collimator, and no evidence of an appreciable deviation from flatness was observed. This, together with the usual test for the fit of two scraped surfaces, convinced us that these surfaces were flat enough when separate and not under stress. Incidentally, the rectilinear motion of the carriage *F* was checked when these observations were made.

The plate-holder was then assembled with a photographic plate of "parallel plate" glass 1.5 mm thick in place. Tilting mirrors with short lever arms showed that contact between the surfaces *OO* and the gelatin surface was approximately complete at a pressure of 25 lb in⁻², because an increase to 30 did not diminish the separation of these surfaces by as much as 0.1 μ . A pressure of 12 was required to expand the rubber tubes. The photographic plate was then replaced by a strip of "parallel plate" glass of the same thickness, without gelatin, and this was examined with the interferometer, the air pressures varying from 20 to 30. The fringe system showed very little change after a pressure of 25 was reached, showing approximately complete contact at this pressure. Though the surface of "parallel plate" glass is not optically perfect, the interferometer could be set so that there were not more than one or two fringes in a distance of 3 cm at any part of the strip. The number of fringes per cm was determined for every centimeter of the useful length of the plate, as the plate holder moved parallel to the plane *OO* in front of the interferometer. This procedure was repeated with several other strips of "parallel plate." The data thus obtained gave no indication of a curvature of the surfaces *OO* which could cause a constant error in measurements of glancing-angles of as much as 0.04". The gelatin surface of ordinary commercial photographic plates, when examined with the interferometer, showed very rapidly changing local curvatures many times greater than any constant curvature that could be introduced by the plate-holder. It is in-

* The perfection of the spectrometer and plate holder is largely due to the painstaking care with which the scraped surfaces were fitted by Mr. Moody of the Pratt and Whitney Company.

teresting to note, in this connection, that when a strip of gelatin was removed from the plate, the fringe system associated with the remaining gelatin was usually continuous with that associated with the glass. This showed that the upper surface of the gelatin conformed pretty generally to the irregularities of the glass surface on which it was coated.

The spectrometer, having been adjusted and tested in the manner described, was next aligned with the source of x-rays. In order to obtain maximum intensity through two very narrow slits, it is necessary that the line of centers of the slits should pass through the center of the most intense region of the focal spot on the target. As the authors have previously shown,⁵ the focal spot is striated when the hot cathode is a spiral filament, being approximately a projection of the turns of the filament on the target. By taking x-ray photographs through S_1 when S_3 was in place and again through horizontal slits substituted for S_1 and S_2 , it was possible to adjust the tube and spectrometer so that the latter was approximately level, and the center line of S_1 and S_2 passed through the center of the most intense region of the focal spot. That this line coincided with the axis XX' , as previously defined, was also checked photographically with the aid of S_3 .

PART III. EXPERIMENTAL PROCEDURE

The crystal used was a calcite rhomb $12 \times 10 \times 7$ mm cleaved from a block of Iceland spar obtained from the "Marsh Collection," Yale University. This specimen is denoted by Ca 1. The largest cleavage face was used for reflection, and, as far as could be found by examinations with reflected light and with a microscope, the portion on which the x-rays fell was a plane. After mounting in the crystal holder with soft wax, this face was adjusted parallel to, and into coincidence with, the axis of rotation within $25''$ and 10μ respectively. A tilt of $25''$ would cause an error in the glancing angle under consideration of $0.0004''$.

Due to refraction, no crystal is a perfectly selective reflector, and therefore a monochromatic beam, upon reflection, will diverge beyond the limits of the rectangular region discussed by Uhler.² A sufficient measure of this divergence was obtained, without using a double crystal method, by comparing the angular width of the incident beam, as calculated from the slit widths, with the angle through which the crystal could be turned while still reflecting some energy of the wave-length under consideration. The limits of this angle were determined by finding the angular settings at which the crystal ceased to give an image on the photographic plate, during an exposure time a little too short to permit the formation of a perceptible image due to white radiation. This angle was approximately $46.8''$, with an extreme variation of less than 10 percent. As the beam was limited by the slits to an angular width of $26''$, the divergence due to the crystal was $20.8''$.

Table I gives a comparison between line widths calculated from the above angle and average line widths measured on the spectrograms, at three different distances from the crystal denoted by the plug numbers on the mea-

suring bar. The plate intersected the reflected beam near the Bragg focus of S_2 and S_1 in the first and third positions respectively and about half way between these foci in the second position. Considering the difficulty of de-

TABLE I. *Line widths at various positions of plate.*

Plug No.	0	6	11
Calculated	0.0249 mm	0.0400 mm	0.0535 mm
Measured	0.0276 "	0.0395 "	0.0519 "

termining line widths, the above figures are in fair agreement and give a reasonable indication of the perfection of the crystal. In practice it was found that a properly filled out image was obtained when the crystal was rotated through an angle of $18''$ symmetrically about the best setting; no additional width accrued due to energy from the wave-length under investigation through using a larger angle.

Uhler² has pointed out that oblique rays in a plane parallel to the axis of rotation of the crystal broaden the image asymmetrically. During the taking of spectrograms, the incident beam was limited by the following conditions: the widths of the two slits S_1 and S_2 were fixed by strips of platinum foil 0.02 mm thick, their lengths were limited to 3.2 and 2.5 mm respectively, and their distances from the crystal were 35.5 and 4.5 cm respectively. Limited thus, the maximum effect of oblique rays on the glancing-angle is the negligible amount of $0.02''$ for an eleven inch displacement.

In order to reduce the values of the glancing-angle obtained from the spectrograms to their values at a standard temperature, it is necessary to know the coefficient of expansion of calcite along the normal to its cleavage planes; i.e., the coefficient a_{18} in the formula $\sin\theta_{18} = \sin\theta_t [1 + a_{18}(t - 18)]$. W. Stenström⁶ gives the generally quoted approximate value of $1.04(10)^{-5}$ per degree centigrade, which is not precise enough to be used to correct data of the accuracy attained today. In obtaining this value, he assumed an angle of 45° between the optic axis and the normal to a cleavage plane, and $2.62(10)^{-5}$ and $-0.54(10)^{-5}$ per degree centigrade respectively for the coefficients parallel and perpendicular to the optic axis. We have recalculated the coefficient using the following constants: the axial angle of the crystal is $101^\circ 55.0' \pm 0.2'$ at 22°C as given by H. N. Beets;⁷ the mean coefficients of expansion parallel and perpendicular to the optic axis are $(\alpha_{\parallel} + 2\beta_{\parallel}t)$ and $(\alpha_{\perp} + 2\beta_{\perp}t)$ respectively where:

$$\begin{aligned}\alpha_{\parallel} &= +2.513\ 53\ (10)^{-5} & \beta_{\parallel} &= +0.001\ 18\ (10)^{-5} \\ \alpha_{\perp} &= -0.557\ 82\ (10)^{-5} & \beta_{\perp} &= +0.000\ 138\ (10)^{-5}\end{aligned}$$

in degrees centigrade as given by Benoît.⁸ The value of the coefficient a_{18} corresponding to these constants is:

⁶ W. Stenström, Dissertation, Lund (1919) p. 38.

⁷ H. N. Beets, Phys. Rev. [2] 25, 621 (1925).

⁸ R. Benoît, Travaux et Memoires du Bureau International des Poids et Mesures 6, 190 (1888).

$$a_{18} = 1.02_8(10)^{-5},^1$$

which, if used over a sixteen degree interval, will give the correction of the glancing-angle for the $K\alpha_1$ line of silver to 18°C within 0.008".

Table II gives $\log_{10}[1 + a_{18}(t - 18)]$ for the interval 10°C to 26°C.

TABLE II. *Temperature correction for calcite.*

A Gaertner measuring engine was used to measure the spectrograms and the distances between the fiducial lines on the measuring bar. The pitch of the screw is approximately 0.5 mm, and the least count of the divided head is 1μ . The errors of the screw were investigated by measuring, on successive parts of the screw, two overlapping 9 mm distances between fine lines on a glass plate manufactured by the Zeiss Company. As both these distances were within less than two divisions of a whole number of turns at all stations, errors of one turn did not enter. The settings were determined with parallel hairs in the eye piece of a three hundred power microscope. The algebraic sums of the residuals from the mean of the 9 mm lengths for successive intervals were plotted against the corresponding 9 mm stations on the screw. The errors so determined all lay within 0.1μ of a smooth curve. The errors in one turn were found at four stations, equally distributed along the screw, by measuring a 0.1 mm interval on the glass plate for successive fifths of the head. These errors are nearly sinusoidal and therefore are eliminated in the mean of three measurements started from three stations on the head, each of which is separated from the others by one third of a turn. As only relative linear measurements are involved in the displacement method, an absolute calibration of the screw was not made, although its units are termed millimeters throughout this paper.

For comparing the measuring bar with the screw the spectrometer microscope was used. The reliability of setting on the lines was found from the maximum variation between settings occurring in each of 143 groups, each group consisting of two to four settings on a line. The maximum variation of setting in one group was 0.9μ , and the average about 0.25μ . Table III gives the frequency of occurrence of the variations of different amount, from 0.1μ to the maximum, for all the groups.

TABLE III. *Frequency of occurrence of large and small variations in setting.*

Frequency of occurrence of a certain variation	25	28	35	23	14	6	8	1	1	2	0
Amount of variation in a group μ	.0	.1	.2	.3	.4	.5	.6	.7	.8	.9	1.0

The maximum amount that any setting differed from the mean in any of the 143 groups was 0.5μ . Thus it appears that, when the plate-holder is displaced by a certain interval on the bar, the chance will be very small that the actual displacement will differ from the measured value of the interval by as much as 1μ , in spite of the fact that the end positions of the interval are determined only once. Such an error in the displacement would cause an error of $0.07''$ in the glancing-angle under consideration.

The following procedure was adopted for obtaining spectrograms. 8×10 plates were cut in strips of the correct size and "*normalized*,"* the edge strips being discarded; after drying, the edges of the gelatin were carefully bevelled by cutting with a sharp knife blade, inclined at a slight angle with the plane of the plate, to remove irregular frills. A plate having been placed in the plate-holder, and the rubber tubes inflated, the holder was mounted on its carriage, with a lead screen so placed as to shield the plate from the lower half of the direct beam. Then the carriage was moved to that one of the desired positions which was most remote from the crystal and adjusted until, when locked, the setting of the microscope cross-hairs on the corresponding fiducial line of the bar appeared exact. After the lapse of at least twelve hours, the setting of the microscope was again scrutinized, but in no case was it necessary to readjust it.

With thermal equilibrium thus assured, the spectrogram was taken. First, with the divided circle set so that the crystal holder did not intercept the incident beam, a short exposure was made to record the upper half of the central image. Then the spectral line was taken on both sides of the direct beam, equal exposures being given for each of five angular positions of the crystal symmetrically spaced about the best setting on each side and covering a range of $18''$; this was repeated for each desired position of the plate-holder. The tangent screw was disengaged from the circle table before making an exposure to avoid unnecessary stress on the cone bearing, and the microscope setting was checked before and after the set of exposures for each spectral image. During each exposure, the temperature of the crystal was recorded from the reading on a calibrated mercury thermometer having five divisions per degree centigrade; this thermometer was so held by a clamp that its bulb was three centimeters from the crystal. After the last spectral image exposure the plate-holder was moved (when necessary) to that station which had been nearest the crystal, and a short exposure was made for the central image with the lead screen moved, and the crystal turned so as not to interfere with the direct beam. The plate-holder was then given a small transverse displacement, and the central image again taken for convenience in measuring the separation of the portions of the central images taken with the holder in its two extreme positions.

During exposures, the current through the x-ray tube was approximately 4 m.a.; and the filament current was regulated so as to maintain a brush

* By *normalizing* we mean soaking the unexposed plate in water for thirty minutes, then in strong ethyl alcohol for twenty minutes and finally leaving it to attain equilibrium in a humid atmosphere. The reasons for subjecting the plates to this process are fully discussed in another paper.¹⁴

discharge, with only occasional sparking, between the blunt points of a six inch spark gap in parallel with the tube. No attempt was made to get a more exact measure of the potential, but these operating conditions assured spectral images of ample density with exposures of moderate duration.

Table IV gives the detailed data recorded during the taking of a typical spectrogram, plate AG2, and Fig. 6 is a drawing to scale of this spectrogram.

8	0	out*					1
9	0	out* (plate-holder displaced sideways 2 mm)					1

Remarks: Developed 4 min at 77°F, fixed 20 min, washed 30 min, rinsed in distilled water 10 min, and soaked in alcohol 20 min at 77°F, then dried in a humid atmosphere.

* Turned to give direct transmission.

After the plates were thoroughly dry, rulings were scribed at intervals on the gelatin surface (the dotted lines in Fig. 6) along a line through the centers of, and normal to, the spectral images, and all measurements were made along this line except those of the central image separation. If the spectral images were not filled out and black, they were discarded. Table

ω between the normal to the plate and the line XX' , computed by Eq. (2) from the data corresponding to the two different displacements, differ in magnitude and sign; but the more precise optical tests had shown very conclusively that the maximum rotation of the plate-holder, for any displacement along the tracks, was less than $2''$. Such differences are, therefore, probably due to residual fortuitous variations in position of a developed image with respect to its corresponding latent image,¹⁴ and the fact that commercial plates cannot be forced flat.

Table VII is given as an illustration of the accuracy with which the spectrograms could be measured. As shown in Table V, the distances be

tween pairs of lines were measured first with the plate in one position on the engine, and again when it was reversed ("top up", "top down"). The numbers tabulated are the differences between the means of these measurements in each position. The first three plates had lines corresponding to

TABLE VII. *Difference between measurements direct and reversed.*

Spectro-gram	Differences		Spectro-gram	Differences	
	11 in. displ.	6 in. displ.		11 in. displ.	6 in. displ.
AG1	0.25 μ	0.29 μ	AG3	0.56 μ	0.04 μ
AG2	0.20 μ	0.44 μ	AG4	0.81 μ	

both 11 and 6 in. displacements, but the fourth had only the former. The measurements on plate AG4 were repeated. If the new measurements are averaged with the first set, the corresponding difference is 0.72 instead of 0.81 μ . If it is assumed that the measurements can be in error by as much as 0.81 μ in the case of the 11 in. displacement, the resulting glancing-angle would be in error by 0.29". The maximum effect on this angle due to the uncertainty of setting on the bar is 0.07". Therefore it seems evident that there is a negligible chance that values of the glancing-angle obtained from different 11 in. displacements can fluctuate, due to errors of measurement, by as much as 0.36", assuming of course good lines on the spectrograms. Re-measurements made after a lapse of three months on another plate, AG5, by an independent observer gave glancing-angle values differing for the 5 and 6 in. displacements by 0.13" and 0.00" respectively.

TABLE VIII. *Effect of method of measurement. Plate No. AG9, 4 in. displacement, taken at 22.1° C. glancing-angle at 18° C.*

Measured at ° C.	Uncorrected for temp. of meas.		Corrected for temp. of meas.		Description of method of measurement
20.5	5° 17'	14.54"	5° 17'	14.42"	Deep focus objective; 57° cross-hairs; 18 X.
21.2	5° 17'	14.41"	5° 17'	14.34"	Same objective; parallel hairs separated to straddle width of remote lines; 18 X.
19.7	5° 17'	14.65"	5° 17'	14.48"	Shallow focus; parallel hairs same; 20 X.
Remote 17.0 Near 19.0	5° 17'	14.95"	5° 17'	14.43"	Same objective, but parallel hairs suitably adjusted to measure separation of remote and near lines independently; 20 X.

Spectral images taken with the plate in a remote position are broader than those taken with it near the crystal; therefore, if parallel hairs of fixed separation are used in the measuring microscope, their adjustment will not

be suitable for both types of images. Plate AG9 was measured under varying conditions of magnification, type of eye-piece and temperature, and Table VIII gives the glancing-angles thus obtained. It will be observed that the second column shows excellent agreement for different methods of measurement, especially when it is borne in mind that for such a short displacement a variation in the image separation of 0.2μ would change the glancing-angle by $0.20''$, and that the near and remote lines were of different width.

PART IV. RESULTS

The final results are given in Table IX. They were obtained from eight spectrograms, six of which were taken with the plate-holder in three, the remainder in only two, positions, but that nearest the crystal was the same for all. All the plates had been cut from the central portions of large plates; AG1 to AG4 from one Eastman "40," AG5 to AG7 from another, and AG9

TABLE IX. *Final data and results. Line; Ag ($K\alpha_1$). Crystal; Calcite (Ca 1).*

Spectro-gram	Displ't inches	Taken at ° C	Glancing-angle at 18° C	Mean values, probable errors of mean and of one determination respectively

DISCUSSION

Of the values given in the table, Kellström's first order determination has the smallest probable error and is the one quoted in the International Critical Tables. The value he gives for the wave-length determined from second order reflection would predict a first order glancing-angle ($5^\circ 17' 14.58'' \pm 0.18''$) approximately midway between his measured first order and ours and with four times his first order probable error. The fact that our value of the glancing-angle differs from his two values, and the latter differ among themselves, by about three times the sum of the respective probable errors would lead one to suspect that any one or all of the values may be affected by a constant error. From the point of view of agreement, the two sensibly identical values of Leide and Lang, large though their probable errors may be, favor our value rather than those of Kellström. The "Method of Displacement" may be subject to an error sufficient to account for our disagreement with Kellström's accepted value if the underlying assumption regarding the symmetry of the reflected beam is not fulfilled. However, the mean value of the glancing-angle computed from the eleven inch displacements only, where the plate was near a Bragg focus in both its positions, is sensibly the same as that from other displacements, where the plate intersected an intermediate portion of the beam in one position (Table IX). This fact confirms our belief that the reflected beam possessed the required symmetry, in spite of the fact that the crystal was not a perfectly selective reflector. The exhaustive tests to which the apparatus was subjected failed to show any defect which could cause an appreciable constant error. The only remaining source of such an error seems to be the crystal. The discrepancy between the results would be accounted for by a difference in grating space of seven parts in a hundred thousand between the crystals used. We have made use of only one specimen of Iceland spar while Kellström has used two (Pk 1 and Pk 2), although most of his data were obtained from Pk 1. He states that both crystals gave the same result within his limits of error. However, in the one case in which he used Pk 2 for a second order determination of the wave-length considered here his result is identical with that of our eleven inch displacements. We have been unable

to find any statement by Leide or Lang giving information concerning the particular specimens of calcite used by them. DeFoe and Compton¹³ have measured the density of specimens of calcite, obtained from various sources, within a probable error of $(10)^{-4}$ gm cm⁻³. They give values for two specimens from Iceland which differ by thirteen times this amount, indicating a real difference in density, even though they allow only half weight to the value for one of these specimens in computing the mean density of all the specimens. If all variations in density are reflected in differences of grating space, a difference in density of $6 \times (10)^{-4}$ gm cm⁻³ (less than half that found by DeFoe and Compton) between Kellström's crystal and ours would be sufficient to account for the difference in the values of the glancing-angle under consideration. The discrepancy might therefore be explained in this way, though it is doubtful that the observed differences in density are really due to variations in grating space.

TABLE XI. *Average variations in measured values of glancing-angle due to various causes.*

Displacements	11 in.	6 in.	5 in.	4 in.
<i>Average variations due to:</i>				
Variations in setting on bar	0.034"	0.06"	0.07"	0.10"
Unflatness of gelatin	0.17	0.31	0.37	0.50
Motions of images after exposure				
if plates are:				
normalized	0.25	0.46	0.56	0.69
not normalized	1.00	1.84	2.24	2.76
<i>Sum of average variations:</i>				
If plates are:				
normalized	0.45	0.83	1.00	1.29
not normalized	1.20	2.21	2.68	3.36
<i>Observed average variations</i>	0.20	0.33	0.30	—
<i>Observed maximum variations</i>	0.47	1.10	0.72	—

It is of interest to consider the effect on the final result of various causes of uncertainty in the directly measured quantities. The average difference between successive settings on the bar was 0.25μ , therefore any displacement of the plate-holder is subject to an average uncertainty of 0.5μ from this cause. Irregularities in the surface of the gelatin would cause the effective displacement to differ from the actual. An interferometer investigation of the gelatin surface of the developed spectrograms, when held in the plate-holder, showed that these irregularities could cause an average error in the displacement of 2.5μ . Our work on the unreliability of position of photographic images¹⁴ showed that the average error in the measured value of a fixed distance, as recorded on photographic plates, was 0.7μ when the plates had been normalized and 2.8μ when they had not. These errors, of course, include both the error of setting and that due to motion of the image. Though the images of the template slits¹⁴ could be set on more accurately than

¹³ O. K. DeFoe and A. H. Compton, Phys. Rev. [2] 25, 618 (1925).

¹⁴ D. Cooksey and C. D. Cooksey, Phys. Rev. preceding article.

spectral images, we shall assume that these figures include the average variations that might be expected in the remeasurement of a spectrogram. The effect of the average variation due to each of these causes on glancing-angle values, calculated for various displacements, is shown in Table XI.

These statistics not only emphasize the advisability of normalizing photographic plates before using them as accurate recorders of distances, but suggest that, even for small glancing-angles, the accuracy of the displacement method would be improved by the use of emulsions coated on good *plate* glass. With the accuracy of setting on spectral images limited as it is, there would seem to be no necessity for resorting to more accurate methods of measuring the displacement. Even though the apparatus is massive and so has a large thermal capacity, there is little doubt that better precautions for maintaining it at a constant temperature would have a beneficial effect. However, the manipulation in the present work was carried out with special reference to making the effects of temperature changes fortuitous.

In conclusion we wish to express our great appreciation of the encouraging and helpful interest shown, during the whole progress of this work, by Professor Uhler and Professor Emeritus Hastings of this department. We are also grateful to Dr. Albert W. Hull of the Research Staff of the General Electric Company for advice in connection with x-ray tubes and filaments, and to Professors McKeehan and Uhler for helpful suggestions in connection with the presentation of this investigation. In directing the construction and exhaustion of x-ray tubes, we have been greatly aided by experience gained in our long association with Mr. Alfred Greiner, formerly connected with this laboratory.

THE SPHERICALLY SYMMETRICAL FIELD IN THE UNIFIED THEORY

BY N. ROSEN AND M. S. VALLARTA

MASSACHUSETTS INSTITUTE OF TECHNOLOGY, CAMBRIDGE, MASSACHUSETTS

(Received May 15, 1930)

ABSTRACT

In this paper a systematic investigation of the spherically symmetrical static field in Einstein's unified theory of the electromagnetic and gravitational fields is given. The investigation is carried through in two cases: with and without time symmetry. By a time symmetrical field we understand one whose Riemann interval is not altered by changing $+dt$ into $-dt$.

To begin with we develop a generalization of the formulas for parallel displacement and covariant affine differentiation in Einstein's geometry which enables us to introduce orthogonal transformations of the local coordinates, so as to bring them formally into agreement with the Gaussian coordinates. We then solve the Einstein field equations $F^{\mu\alpha}=0$ and $G^{\mu\alpha}=0$, first without the assumption of time symmetry. We determine the values and the physical significance of the constants of integration by considering the case of a very weak field, and obtain asymptotically the classical Coulomb field (e/r^2) and the classical Newtonian potential ($-m/r$). Positive and negative electricity appear in the unified theory as given empirical facts, just as in the classical theory. In the present theory, however, the Newtonian field and the Coulomb field can be separated only asymptotically. In the immediate vicinity of a charged mass particle they are inextricably bound together.

Our solution gives a quadruple ("Vierbein")

$$\begin{aligned} {}_1h^1 &= 1 + e^2/r^4, & {}_2h^2 &= 1, & {}_3h^3 &= 1, \\ {}_4h^4 &= -(ie/r^2)(1 + e^2/r^4)^{1/2}, & {}_4h^4 &= 1 + m \int_r^\infty r^{-2}(1 + e^2/r^4)^{-3/2} dr. \end{aligned}$$

All the other components vanish. By a transformation of variables this is shown to reduce to the quadruple recently calculated by Einstein and Mayer.

The field equations are then solved with the assumption of time symmetry. The electrostatic field vanishes, but the component g_{44} of the metric form has approximately the Schwarzschild value, while the others have the Euclidean values. Because of the absence of a law of motion, no observable predictions having to do with the path of an exploring particle can be made. It is shown, however, that in the unified field the theory gives in the first approximation the same red shift as the 1916 theory. If it is assumed that the orbit of a planet is a Riemannian geodesic, as in the 116 theory, then the advance of the perihelion of Mercury comes out approximately 7" per century, that is, about the same as in the 1905 theory.

I. INTRODUCTION

A NUMBER of papers have recently appeared bearing on Einstein's attempt to construct a unified theory of the electromagnetic and the gravitational fields. The geometrical foundations of the new theory were laid down by Einstein in 1928,¹ without knowledge of the previous work of

¹ A. Einstein, Sitz. d. preuss. Akad. d. Wiss., 1928, p. 217; also Math. Ann. 102, 685, (1930), hereafter referred to as "E.1." The reader is referred to this paper for explanation of the symbols and operations used in the present article.

Cartan and others on the same subject.² In a paper following immediately thereafter Einstein³ suggested a unified field theory of the electromagnetic and gravitational fields in which the former was defined, in terms of the fundamental tensor h_s^λ of a torsion geometry with distant parallelism, through an electromagnetic potential $\phi_\lambda = \Lambda_{\lambda\sigma}^\sigma$, where $2\Lambda_{\lambda\mu}^\sigma = h_s^\sigma(h_{\lambda,\mu}^s - h_{\mu,\lambda}^s)$, and the latter through the usual gravitational potentials $g_{\mu\nu}$ defined in terms of the fundamental quantities h_λ^s by the relation $g_{\lambda\mu} = h_\lambda^s h_{s\mu}$. He further suggested a set of field equations for the determination of the tensor h_s^λ , obtained from the variational equation

$$\delta \int h g^{\mu\nu} \Lambda_{\mu\beta}^\alpha \Lambda_{\nu\alpha}^\beta d\tau = 0. \quad (1)$$

The spherically symmetrical statical field in the unified theory was then investigated by Wiener and Vallarta.⁴ In accordance with Einstein's definitions of the electric and gravitational fields, one had to expect that in the time symmetrical case one should obtain the Schwarzschild solution for the gravitational field of an uncharged mass particle, the Nordström-Jeffery solution⁵ for the charged mass particle and, asymptotically the classical potential $\pm e/r$ for the electrostatic field. Instead they found that in this case, adopting Einstein's definition of the electromagnetic potential, the electrostatic field vanishes and, further, the gravitational field obtained by solving the field equations (1) also vanishes. One of the present authors⁶ then pointed out that the vanishing of the electrostatic field is a consequence of the definition of the potential and has nothing to do with the particular choice of the field equations.

In 1929 Einstein modified his field equations several times. His first paper of that year⁷ contains a second set of field equations which leads, as shown by Salkover⁶, to the Schwarzschild solution for the gravitational field in the first approximation. In his second paper of that year Einstein⁸ gave a third set of field equations based on a new Hamiltonian. Wiener, in an unpublished paper, was then able to show that this new Hamiltonian is, except for nonsignificant terms, precisely the Hamiltonian of the gravitational theory of 1916, and therefore leads to the gravitational field described by the Schwarzschild solution. Wiener also showed that Levi-Civita's⁹ definition

of the electric vector leads to a vanishing spherically symmetrical, time symmetrical electrostatic field.

The development of the theory entered a new phase with Einstein's 1930 papers. Giving up the previous attempt to describe the electromagnetic field in terms of a potential ϕ_μ and also, as it appears, the description of the gravitational field in terms of the potentials $g_{\mu\nu}$, except in the case of a weak field, he suggested a fourth set of field equations to determine the fundamental tensor h_s^{λ} .¹⁰ The present paper is concerned with the solution of these field equations in the spherically symmetrical case, with and without time symmetry. It will be shown that the former case leads to a vanishing electrostatic field, while the latter gives, asymptotically, the classical Coulomb field. We believe this is the first instance where the asymmetry of past and future has played a fundamental role in a *field* theory. Positive and negative electricity appear in the unified theory as *given* empirical facts, just as in classical theory. Both cases, with and without time symmetry, give asymptotically the classical Newtonian potential. By making a suitable transformation of variables we show that the quadruple ("Vierbein") obtained without the assumption of time symmetry is identical with that found by Einstein and Mayer¹¹ by a different method.

Comparison with experimental evidence having to do with the motion of an exploring particle is impossible at the present stage, because the law of motion has not yet been discovered, but it may be conjectured on the basis of our present results that the path of an uncharged exploring particle in the pure gravitational field is not a geodesic with respect to the Riemannian ds^2 as in the 1916 theory. However, the unified theory leads to predict a shift of spectral lines towards the red which in the first approximation agrees with that of the 1916 theory.

II. MATHEMATICAL INTRODUCTION

In problems involving spherical symmetry it is usually found that a considerable simplification is achieved if spherical space coordinates r , ϕ , θ are used to locate a point in the field. In the Einstein geometry as formulated by him this immediately leads to a difficulty, because he does not allow orthogonal transformations of the local quadruples ("Vierbeine") so that locally and at each point the local coordinates may formally be made to agree with the Gaussian coordinates. If local orthogonal transformations are made use of certain formal generalizations are necessary which we now proceed to establish.

Let $g_{\alpha\beta}$ and γ_{ab} be the fundamental metric tensors in the Gaussian and in the local (Euclidean or pseudo-Euclidean) system, respectively. We place following De Donder¹² and Wiener and Vallarta⁴ and using the customary tensor notation:

¹⁰ A. Einstein, Sitz. d. preuss. Akad. d. Wiss. 1930, p. 3; also E.1.

¹¹ A. Einstein and W. Mayer, Sitz. d. preuss. Akad. d. Wiss., p. 110, 1930; hereafter referred to as "E-M".

¹² T. De Donder, Comptes rendus, 1928, p. 817.

$$g_{\mu\nu} = \gamma^{ab} h_{a\mu} h_{b\nu} = h_{\mu}^b h_{b\nu} \quad (2)$$

$$g^{\mu\nu} = \gamma_{ab} h^{a\mu} h^{b\nu} = h_{\mu}^a h^{b\nu}. \quad (2a)$$

In these expressions Latin indices refer to the local system, Greek indices to the Gaussian system. The quantities $h_{a\mu}$ have thus tensorial character both in the local and in the Gaussian systems, but in raising or lowering local (Latin) indices, the local tensor γ_{ab} is used, whereas in the case of Gaussian (Greek) indices, the tensor $g_{\mu\nu}$ is used. In Einstein's papers where local Cartesian coordinates are used the distinction between co- and contravariant local indices does not occur. The transformation formulas from the local to the Gaussian system now become

$$A^\nu = h_s^\nu A^s = h^{s\nu} A_s, \quad A_\nu = h_\nu^s A_s = h_{s\nu} A^s \quad (3)$$

$$A^s = h_\mu^s A^\mu = h^{s\mu} A_\mu, \quad A_s = h_{s\mu} A^\mu = h_s^\mu A_\mu \quad (4)$$

and we have, as usual,

$$h_{s\mu} h^{s\nu} = h_\mu^s h_s^\nu = \delta_\mu^\nu, \quad h_s^\mu h_\mu^t = h_{s\mu} h^{t\mu} = \delta_s^t$$

where δ_ν^μ is the Kronecker symbol. Hence

$$A^2 = A_s A^s = (h_{s\mu} A^\mu)(h_\nu^s A^\nu) = \gamma_{st} h_\mu^t h_\nu^s A^\mu A^\nu = g_{\mu\nu} A^\mu A^\nu = A_\mu A^\mu$$

and the transformation formulas (3), (4), are shown to be compatible with the definition (2). Similar transformation formulas can be given for tensors of higher rank. Thus whether one works with local coordinates (Levi-Civita) or Gaussian coordinates (Einstein) is largely a matter of choice and convenience.

We now derive the generalized law of parallel displacement which formally allows local orthogonal transformations.¹³ The change δ of the local components of a vector (or tensor) for an infinitesimal displacement is, in accordance with the postulate of distant parallelism,

$$\delta A_s = \delta(h_{s\alpha} A^\alpha) = \delta(h_s^\alpha A_\alpha) = 0 \quad (5)$$

which gives

$$h_{s\alpha} \delta A^\alpha + h_{s,\beta}^\alpha A^\alpha \delta x^\beta = 0$$

$$h_s^\alpha \delta A_\alpha + h_{s,\beta}^\alpha A_\alpha \delta x^\beta = 0$$

where the dot indicates covariant differentiation referred to the local coordinates, i.e. to the form $\gamma_{ab} dx^a dx^b$. From this we obtain

$$\delta A^\alpha = -A^\sigma \Gamma_{\sigma\beta}^\alpha \delta x^\beta \quad (6)$$

$$\delta A_\alpha = A_\sigma \Gamma_{\alpha\beta}^\sigma \delta x^\beta \quad (6a)$$

where

$$\Gamma_{\sigma\beta}^\alpha = h^{s\alpha} h_{s\sigma,\beta} = -h_{s\sigma} h^{s\alpha}_{,\beta} \quad (7)$$

and

$$h_{s\sigma,\beta} = h_{s\sigma,\beta} - \{s\beta, t\} h_{t\sigma} - \{\sigma\beta, \alpha\} h_{s\alpha}. \quad (7a)$$

¹³ N. Rosen, "The Use of Polar Coordinates in Einstein's Geometry." S. M. Thesis, Mass. Institute of Technology; June, 1930.

As already mentioned above, the Christoffel symbols are defined through the tensor γ_{ab} by the usual formula

$$\{st, u\} = \gamma^{ub} [st, b] = \frac{1}{2} \gamma^{ub} \left(\frac{\partial \gamma_{sb}}{\partial x^t} + \frac{\partial \gamma_{tb}}{\partial x^s} - \frac{\partial \gamma_{st}}{\partial x^b} \right).$$

It is clear that a local orthogonal transformation can always be made whereby $\gamma_{ab} = \delta_{ab}$. Then obviously all the Christoffel symbols vanish and $h_{s\sigma, \beta} = h_{s\sigma, \beta}$ further $\Gamma_{\mu\nu}^\sigma = h^{s\sigma} h_{s\mu, \nu}$, in accordance with Einstein's definition (E.1, p.688, Eq. (12)). $\Gamma_{\mu\nu}^\sigma$ is in general different from $\Gamma_{\nu\mu}^\sigma$ and it can be readily shown that if $\Gamma_{\mu\nu}^\sigma = \Gamma_{\nu\mu}^\sigma$ then the space whose metric is defined by the $g_{\mu\nu}$ is Euclidean.

The law of covariant affine differentiation will now be derived. Since the local components A_s of a vector are covariant relatively to a transformation of the local coordinates, $A_{s, \alpha}$ is a tensor. Therefore $(h_s^\sigma A_\sigma)_{, \alpha}$ and

$$h_s^\sigma{}_{, \alpha} A_\sigma + A_{\sigma, \alpha} h_s^\sigma$$

or

$$A_{\tau, \alpha} + A_\sigma h_s^\sigma{}_{, \alpha} h_\tau^s = A_{\tau, \alpha} - A_\sigma h_{s\tau, \beta} h^{s\sigma} = A_{\tau, \alpha} - A_\sigma \Gamma_{\tau\beta}^\sigma \quad (8)$$

are tensors. This tensor we shall call the covariant affine derivative of A_τ with respect to x^α and denote it by $A_{\tau; \alpha}$. Analogously for a contravariant vector

$$A_{; \tau}^\sigma = A_{, \tau}^\sigma + A^\alpha \Gamma_{\alpha\tau}^\sigma, \quad (9)$$

which can readily be generalized to a tensor of any rank. From this we may also obtain the divergence $A^\sigma{}_{; \sigma}$ which is merely the contracted affine derivative.

If we take a scalar invariant Ψ and differentiate it covariantly twice we obtain

$$\begin{aligned} \psi_{; \alpha} &= \psi_{, \alpha} = \psi_{, \alpha} \\ \psi_{; \alpha; \beta} &= \psi_{; \alpha, \beta} - \psi_{; \sigma} \Gamma_{\alpha\beta}^\sigma = \psi_{, \alpha, \beta} - \{\alpha\beta, \sigma\} \psi_{; \sigma} - \psi_{; \beta} \Gamma_{\alpha\sigma}^\sigma \end{aligned}$$

hence interchanging α and β

$$\psi_{; \beta; \alpha} = \psi_{, \beta, \alpha} - \{\beta\alpha, \sigma\} \psi_{; \sigma} - \psi_{; \sigma} \Gamma_{\beta\alpha}^\sigma$$

and subtracting

$$\psi_{; \alpha; \beta} - \psi_{; \beta; \alpha} = \psi_{; \sigma} (\Gamma_{\alpha\beta}^\sigma - \Gamma_{\beta\alpha}^\sigma).$$

Therefore $\Gamma_{\alpha\beta}^\sigma - \Gamma_{\beta\alpha}^\sigma$ is a tensor of the third rank, once contravariant and twice covariant. We denote it by $\Lambda_{\alpha\beta}^\sigma$. By (7) and (7a) we have

$$\Lambda_{\alpha\beta}^\sigma = h^{s\sigma} (\{s\alpha, t\} h_{t\beta} - \{s\beta, t\} h_{t\alpha} + h_{s\alpha, \beta} - h_{s\beta, \alpha}) \quad (10)$$

Einstein originally assumed that the contracted tensor $\Lambda_{\alpha\sigma}^\sigma$ plays the role of the electromagnetic potential, but has now given up this assumption (E.1, p. 691). The tensor $\Lambda_{\nu\sigma}^\mu$, however, plays a fundamental role in the unified theory.

III. THE FIELD EQUATIONS AND THEIR SOLUTION

Einstein sets for his field equations (E.I p. 693):

$$F^{\mu\alpha} = 0, \quad G^{\mu\alpha} = 0$$

where $F^{\mu\alpha} = \Lambda^{\nu\mu\alpha}_{;\nu}$ and $G^{\mu\alpha} = \Lambda^{\alpha\mu\nu}_{;\nu} - \Lambda^{\sigma\mu\tau}\Lambda_{\sigma\tau}^{\alpha}$. For the purposes of this paper it is more convenient to write them $F_{\mu\alpha} = 0$ and $G_{\alpha\mu} = 0$. We now solve these equations under the assumption that time is not symmetrical. Wiener and Vallarta⁴ have suggested that for this case the covariant quadruple has the form*

$$\begin{aligned} {}^1h_1 &= U, & {}^1h_4 &= M, & {}^2h_2 &= 1 \\ {}^3h_3 &= 1, & {}^4h_1 &= N, & {}^4h_4 &= W \end{aligned} \quad (11)$$

where U, M, N, W are functions of r only. Transformed to Cartesian coordinates the contravariant quadruple h_s^λ becomes, as they have shown

$$\begin{aligned} h_s^\gamma &= x_s x_\gamma E(r) + \delta_{s\gamma}(s, \gamma = 1, 2, 3), \quad {}^4h^\gamma = G(r)x_\gamma \\ h_s^4 &= H(r)x_s, \quad {}^4h^4 = F(r) \end{aligned} \quad (12)$$

where $r = x_\gamma x_\gamma (\gamma = 1, 2, 3)$. This quadruple satisfies the Einstein-Mayer conditions (E-M, p. 112, Eq. (15); p. 113, Eq. (22). Since we include improper rotations their $C(r) = 0$. By a transformation of variable $x_4' = x_4 + \Psi(r)$, with Ψ arbitrary, we can always make h_s^4 vanish. Hence we may place without loss of generality $H = 0$, or $N = 0$.

The components of the tensor γ_{ab} are:

$$\gamma_{11} = 1, \quad \gamma_{22} = r^2 \sin^2 \theta, \quad \gamma_{33} = r^2, \quad \gamma_{44} = 1, \quad \gamma_{ab} = 0 \quad (a \neq b) \quad (13)$$

therefore the components of the tensor $g_{\mu\nu}$ are, from (2),

$$g_{11} = U^2, \quad g_{14} = g_{41} = UM, \quad g_{22} = r^2 \sin^2 \theta, \quad g_{33} = r^2, \quad g_{44} = M^2 + W^2 \quad (14)$$

and all the others vanish. Since g_{14} is not zero a change of sign of the variable t changes the sign of the term involving g_{14} in the metric fundamental form. If the variable t is to have its usual relativistic significance, time, then this can only mean that the asymmetry of past and future plays a role in the unified theory. As a matter of fact we shall see later that the condition for the existence of the electrostatic field of a particle is that there be non-symmetrical terms in time in the Riemann interval.

The tensor $\Lambda_{\nu\sigma}^\mu$ has the following non-vanishing components:

$$\begin{aligned} \Lambda_{14}^1 &= -\Lambda_{41}^1 = (MW' - M'W)/UW, & \Lambda_{13}^3 &= -\Lambda_{31}^3 = (U - 1)/r \\ \Lambda_{12}^2 &= -\Lambda_{21}^2 = (U - 1)/r, & \Lambda_{34}^3 &= -\Lambda_{43}^3 = -M/r \\ \Lambda_{24}^2 &= -\Lambda_{42}^2 = -M/r, & \Lambda_{14}^4 &= -\Lambda_{41}^4 = -W'/W \end{aligned} \quad (15)$$

where the prime indicates differentiation with respect to r .¹⁴ From these we find, after some calculation, the field equations:

* To avoid confusion we write in this and similar cases the local indices to the left of the symbols ${}^a h_\lambda$, and the Gaussian indices to the right.

$$F_{14} = -F_{41} = (1/U^2W^2)(MUWW'' - M''UW^2 - MUW'^2 - MU'WW' + M'UWW' + M'U'W^2) + 2(M - M'r)/r^2 = 0. \quad (16)$$

All the other components of the tensor $F_{\mu\nu}$ vanish identically. From the second field equation $G_{\alpha}{}^{\mu} = 0$ we find:

$$G_1^1 = 2(1 - U)/Ur^2 + (1/U^3W^4)(MM''UW^2 - M^2UWW'' + MUW'^2 + M^2U'WW' - MM'U'W^2 - M'^2UW^2) = 0. \quad (17)$$

$$G_1^4 = (1/U^2W^4)(MUWW'' - MU'WW' - MUW'^2 - M'UWW') = 0 \quad (18)$$

$$G_2^2 = (1/r^2U^3W^3)(2M^2U^2W - 2M^2UW - M^2U'Wr - 2M^2U^3W + 4U^2W^3 - 2UW^3 - U'W^3r - 2U^3W^3 + MM'UWr - M^2UW'r) = 0 \quad (19)$$

$$G_3^3 = G_2^2 = 0 \quad (19a)$$

$$G_4^1 = -[(M^2 + W^2)/U^4W^3](MUWW'' - M''UW - MU'W'^2 - MU'WW' + M'UWW' + M'U'W^2) + (2/Ur)[(M'W - MW')/UW - M/r] - (M^2 + W^2)(M'W - MW')W'/U^3W^4 - M(MW' - M'W)^2/U^3W^4 = 0 \quad (20)$$

$$G_4^4 = (1/U^3W^4r)(M^2UWW''r + UW^3W''r - M^2UW'^2r - M^2U'WW'r - 2UW^2W'^2r - U'W^3W'r + 2U^2W'W^3 - MM'UWW'r) = 0 \quad (21)$$

and all the other components of this tensor vanish identically.

From (16) we obtain

$$\frac{d}{dr}\left(\frac{M'W - MW'}{UW} + \frac{2M}{r}\right) = 0, \quad \phi_4 = \Lambda_{4\sigma}{}^{\sigma} = \text{const.} = c_1 \quad (22)$$

verifying the Einstein-Mayer relation $\phi_i = \text{const.}$ (E.-M., p. 115, Eq. (34)).

Since at infinity space is Euclidean we have the boundary conditions: for $r \rightarrow \infty$, $M \rightarrow 0$, $M' \rightarrow 0$, $U \rightarrow 1$, $W \rightarrow 1$. Hence $c_1 = 0$ and

$$W'/W = M'/M + 2U/r. \quad (23)$$

From (18) we have

$$W'/MUW = c_2 \quad (24)$$

and substituting in (21) we obtain

$$MW'r - 2MUW - M'Wr = 0 \quad (25)$$

verifying (23). $G_{\alpha}{}^{\mu} = 0$ is therefore compatible with $F^{\mu\alpha} = 0$ provided that c_1 vanishes, independently of the boundary conditions.

Substituting (23) in (17), or in (20), gives

$$W^2 = M^2/(U - 1) \quad (26)$$

whose logarithmic derivative is $2W'/W = 2M'/M - U'/(U - 1)$. Substituting W'/W from (23) we have $dU/(U - 1) = -4dr/r$ whose integral is

$$U = 1/(1 + c_2^2/r^4) \quad (27)$$

¹⁴ From these we readily find $\phi_1 = \Lambda_{1\sigma}{}^{\sigma} = 2(U - 1)/r - W'/W$, $\phi_2 = 0$, $\phi_3 = 0$, $\phi_4 = (M'W - MW')/UW + 2M/r$ as in a previous paper by Wiener and Vallarta. Here $\Lambda_{\nu\sigma}{}^{\mu} = \Gamma_{\nu\sigma}{}^{\mu} - \Gamma_{\sigma\nu}{}^{\mu}$, whereas in the previous paper $2\Lambda_{\nu\sigma}{}^{\mu} = \Gamma_{\nu\sigma}{}^{\mu} - \Gamma_{\sigma\nu}{}^{\mu}$.

where c_3^2 is an integration constant. We then have from (24), (26), (27) and the boundary conditions

$$1/W = 1 + c_4 \int_r^\infty r^{-2} (1 + c_3^2/r^4)^{-3/2} dr \quad (28)$$

where $c_4 = -ic_2c_3$. From (24) or (26)

$$1/M = (1/ic_3) \left(1 + c_4 \int_r^\infty r^{-2} (1 + c_3^2/r^4)^{-3/2} dr \right) r^2 (1 + c_3^2/r^4)^{1/2} \quad (29)$$

and we finally obtain the quadruple

$$\begin{aligned} {}_1h^1 &= 1/U = 1 + c_3^2/r^4, \quad {}_2h^2 = 1, \quad {}_3h^3 = 1 \\ {}_4h^1 &= -M/UW = -(ic_3/r^2)(1 + c_3^2/r^4)^{1/2}, \\ {}_4h^4 &= 1/W = 1 + c_4 \int_r^\infty r^{-2} (1 + c_3^2/r^4)^{-3/2} dr. \end{aligned}$$

All the other components vanish.

IV. CASE OF A WEAK FIELD AND DETERMINATION OF THE INTEGRATION CONSTANTS

For large values of r the quadruple $h_s{}^\lambda$ becomes

$${}_1h^1 = 1, \quad {}_2h^2 = 1, \quad {}_3h^3 = 1, \quad {}_4h^1 = -ic_3/r^2, \quad {}_4h^4 = 1 + c_4/r. \quad (30)$$

Einstein has suggested (E.I, p. 695) that in the first approximation the gravitational field is represented by $g_{\alpha\lambda}^* = h_{\alpha\lambda}^* + h_{\lambda\alpha}^*$, where $h_{\alpha\lambda}^*$ is an infinitesimal of the first order defined by $h_{\alpha\lambda}^* = \delta_{\alpha\lambda} h_{\alpha\lambda}^*$, $h_{s\alpha}^* = \delta_{s\alpha} - h_s^\alpha$. To the same approximation the electromagnetic field is defined by $a_{\alpha\mu}^* = h_{\alpha\mu}^* - h_{\mu\alpha}^*$. In the case we are considering all the components of $a_{\alpha\mu}^*$ vanish except the components a_{41}^* , a_{14}^* which give $a_{14}^* = -a_{41}^* = -ic_3/r^2$. If we now interpret this as the ordinary electromagnetic tensor then $a_{14}^* = -iE_r$. Asymptotically this should coincide with the Coulomb field for which $E_r = e/r^2$, hence the constant c_3 is to be interpreted as the electric charge. We note that this constant may be taken either positive or negative. Therefore positive and negative electricity must be taken in this theory as an empirical fact, just as in classical theory.

If we keep terms of the order $1/r$ only, all the components of the tensor $g_{\mu\nu}^*$ vanish except g_{44}^* which becomes $g_{44}^* = -2c_4/r$. To this order of approximation we may identify $g_{44}^*/2$ with the Newtonian potential as in the gravitational theory of 1916.¹⁵ Then the integration constant c_4 is to be interpreted as the gravitational mass.

Expanding in a power series we obtain, from (27), (28), (29):

$$\begin{aligned} U &= 1 - e^2/r^4 + \dots \\ 1/W &= 1 + m/r + (3/10)me^2/r^5 + \dots \\ M &= (e/r^2)(1 - m/r + m^2/r^2 + \dots). \end{aligned} \quad (31)$$

¹⁵ A. Einstein "Die Grundlagentheorie der allgemeinen Relativitätstheorie," p. 57, Leipzig, Barth, 1916.

From these expressions it is immediately seen that the electric and gravitational fields of a charged mass particle cannot be separated except when the distance r becomes sufficiently large. In the immediate neighborhood of the particle one cannot speak separately about a Coulomb field and a Newtonian field, as in classical theory, because they are inextricably bound together. This may be of importance in problems having to do with the stability of the nucleus and the constitution of the electron, but the time does not seem to have yet arrived when such problems can be treated quantitatively on the basis of the present theory, for reasons to be briefly discussed below.

V. COMPARISON WITH THE RESULTS OF EINSTEIN AND MAYER

With the interpretation of the integration constants obtained in the preceding section our quadruple becomes

$${}_1h^1 = 1 + e^2/r^4, \quad {}_2h^2 = 1, \quad {}_3h^3 = 1$$

$${}_4h^1 = - (ie/r^2)(1 + e^2/r^4)^{1/2}, \quad {}_4h^4 = 1 + m \int_r^\infty r^{-2}(1 + e^2/r^4)^{-3/2} dr.$$

To show the identity between our results and those of Einstein and Mayer we first make the transformation $x_4 = ix'_4$, both in the local and the Gaussian variables. The only component affected is ${}_4h^1$ which becomes

$${}_4h^1 = (e/r^2)(1 + e^2/r^4)^{1/2}.$$

We next revert to Cartesian coordinates, obtaining the quadruple (12) with

$$E = - (U - 1)/Ur^2, \quad F = 1/W, \quad G = - M/rUW$$

Lastly we make the transformation of the Gaussian space coordinates

$$x'^\alpha = e^{\int (u-1) d\tau/r} x^\alpha = (1 + e^2/r^4)^{1/4} x^\alpha \quad (\alpha = 1, 2, 3)$$

Remembering that h_s^γ transforms as a contravariant vector with respect to a change of Gaussian variables, i.e. according to the usual formula

$$(h_s^\gamma)' = h_s^\sigma \frac{\partial x'^\gamma}{\partial x^\sigma}$$

we obtain the quadruple

$$({}_1h^1)' = ({}_2h^2)' = ({}_3h^3)' = (1 - e^2/r'^4)^{-1/2}$$

$$({}_1h^4)' = ex'/r'^3(1 - e^2/r'^4)^{1/4}, \quad ({}_2h^4)' = ey'/r'^3(1 - e^2/r'^4)^{1/4},$$

$$({}_3h^4)' = ez'/r'^3(1 - e^2/r'^4)^{1/4}, \quad ({}_4h^4)' = 1 + m \int_{r'}^\infty r'^{-2}(1 + e^2/r'^4)^{1/4} dr'.$$

where $r'^2 = x'^2 + y'^2 + z'^2$. All the other components vanish. This is precisely the solution obtained by Einstein and Mayer by a different method.

VI. THE TIME SYMMETRICAL FIELD

By a time symmetrical field we understand one whose Riemann interval is not altered by changing $+dt$ into $-dt$. The condition for time symmetry is therefore that all the components of the tensor $g_{\mu\nu}$ shall vanish whenever either $\mu=4$ or $\nu=4$ except when $\mu=\nu=4$. This requires that $M=0$.

We solve the field equations $F^{\mu\alpha}=0$, $G_{\alpha}{}^{\mu}=0$ under this assumption. Without going into the detail of the calculations, which have already been reported at length in the preceding pages, we note the results: All the components of the tensor $F^{\mu\nu}$ vanish identically. The components of $G_{\alpha}{}^{\mu}$ which do not vanish identically are G_1^1 , G_2^2 , G_3^3 , G_4^4 . From these we get the equations:

$$G_1^1 = -2(U-1)/Ur^2 = 0$$

$$G_2^2 = G_3^3 = -[2(U-1)^2 + U'r/U](1/U^2r^2) = 0$$

$$G_4^4 = (1/U^3W^3r)(UWW''r - U'WW'r - 2UW'^2r + 2U^2WW') = 0.$$

The first equation admits evidently the only solution $U=1$, which is also a solution of the second. From the third we obtain $W'' - 2W'^2/W + 2W'/r = 0$ from which $W'r^2/W^2 = \text{const} = c_1$ and $1/W = c_1/r + c_2$. Using the boundary condition $1/W=1$ for $r \rightarrow \infty$ gives $c_2=1$; hence $W=1/(c_1/r+1) = 1 - c_1/r$ approximately. As before c_1 may be interpreted as the gravitational mass by noting that in a weak field g_{44}^* is twice the Newtonian potential. The quadruple is in this case:

$${}_1h^1 = U^{-1} = 1, \quad {}_2h^2 = 1, \quad {}_3h^3 = 1, \quad {}_4h^4 = W^{-1} = (m/r + 1).$$

All the other components vanish.

It is seen that in this case we obtain asymptotically the Newtonian potential just as in the previous case without time symmetry, but now there is no asymptotic electric field since all the components of $a_{\mu\nu}^*$ vanish. Thus the existence of an electrostatic field in the unified theory depends on the asymmetry of past and future ($-dt$ and $+dt$). We believe that this is the first instance that this asymmetry has been found to have any physical significance in connection with a field theory. The existence of the gravitational field, on the other hand, is apparently not connected with this asymmetry. We may perhaps have found here the fundamental difference, superficial similarity notwithstanding, between the gravitational and the electric field of a charged mass particle.

VII. CONCLUDING REMARKS

In the absence of a law of motion, not yet discovered, the path of an exploring particle in the unified field cannot be calculated. If it were assumed, for instance, that the orbit of a mass particle in a pure gravitational field is a geodesic with respect to the Riemannian ds^2 , as in the 1916 theory, then a simple calculation shows that in the case of Mercury the advance of the perihelion would be $7''$ per century, approximately. For the same reason the path of a light ray in the solar field cannot be predicted. If it were assumed that the path is a geodesic of zero length with respect to the Riemannian

nian interval, as in the 1916 theory, then the present experimental evidence would likewise furnish proof against rather than for the unified theory.

The shift of spectral lines towards the red, on the other hand, does not depend on the law of motion of an exploring particle, but only on the component g_{44} of the Riemann metric. One sees immediately from (14) and (31) that the red shift obtained on the basis of the present theory is the same to a first approximation as that predicted on the basis of the 1916 theory. To higher orders of approximation the present theory would lead to expect an effect depending also on the electric charge, but it seems difficult to devise an experiment to test this conclusion. In addition to the first order effect just discussed, the only evidence in favor of the unified theory seems to be that asymptotically it yields the classical Coulomb field and the classical Newtonian potential.

The two burning questions connected with the unified theory are, first, the discovery of the law of motion and, second, the discovery of a connecting link with quantum theory. The solution of these problems will inevitably lead to crucial experimental tests of its physical significance. While still far from the goal of investigations which we have pursued for some time, a few remarks may properly find expression at this time.

Because of the non-linear character of the field equations it is to be expected, just as in the case of the 1916 theory of gravitation, that these equations and the law of motion are not independent. If this conjecture is correct, then a systematic investigation by the method of Lanczos must lead either to the law of motion or to the proof that there is none. It should be emphasized that the choice of a law of motion is a considerably more difficult matter in the present theory than in the 1916 theory, because in the latter case the Riemannian geodesic is the natural generalization of the Euclidean straight line, so that even without a systematic investigation one would expect on the basis of the Principle of Equivalence that the path of the exploring particle is a geodesic. Such is not the case in the unified theory because there are too many intrinsically defined lines in the Einstein geometry, not merely the Riemannian geodesics, which asymptotically reduce to Euclidean straight lines. Hence the difficulty of finding the law of motion without a systematic investigation.

Until recently there seemed to be little doubt that the connecting link between the unified theory and quantum theory would be found through some generalization of the Dirac equations, as suggested by Wigner, Wiener and Vallarta, Tamm, Fock, Weyl and others. None of these attempts has proved satisfactory and some of them have been shown to be definitely erroneous. An entirely new method of attack, however, has been opened by the quantum electrodynamics of Heisenberg, Pauli, Jordan, and Fermi, but even then no great progress seems possible before this theory has been divested of its extreme formalism. A further discussion of these questions would evidently be very much out of place here, but we hope to return to them in the not too distant future.

THE GIBBS-DALTON LAW OF PARTIAL PRESSURES

BY LOUIS J. GILLESPIE

RESEARCH LABORATORY OF PHYSICAL CHEMISTRY, MASSACHUSETTS
INSTITUTE OF TECHNOLOGY*

(Received May 20, 1930)

ABSTRACT

Various formulations of Dalton's law are investigated thermodynamically. The Gibbs formulation is shown equivalent to the statement: The concentration of a gas is the same at equilibrium on either side of a membrane permeable to it alone. The ordinary form of Dalton's law has only a limited equivalence with the Gibbs form. The Lewis and Randall rule of fugacity is shown in many ways analogous to the Gibbs-Dalton law. Application to experimental data shows that the Gibbs-Dalton law, like the Lewis and Randall rule, though possible for gases which do not follow Boyle's law, is only an approximation. In the cases examined, the errors are opposite in sign to those of the Lewis and Randall rule. An outline is given for the application of the Gibbs-Dalton law to the study of equilibrium in gases, and the useful field of application is indicated.

1. THERMODYNAMIC THEORY

GIBBS formulated Dalton's law as follows:¹ "The pressure in a mixture of different gases is equal to the sum of the pressures of the different gases as existing each by itself at the same temperature and with the same value of its potential." He states "It is in this sense that we should understand the law of Dalton, that every gas is as a vacuum to every other gas." A study of Dalton's paper² shows that the spirit of Dalton's principle is very closely represented in the Gibbs formulation, which will hereinafter be called the Gibbs-Dalton law.

The Gibbs-Dalton law is in sharp contrast to the formulations now commonly given, which either omit entirely the essential idea of equilibrium,³ implied in the phrase "at the same temperature and with the same value of its potential," or state⁴ laws of vapor pressure of liquids in contact with inert gases, which laws assume zero the effects of varying pressure and composition, equations for which were given by Poynting and Raoult.

Gibbs disentangled the essential principle from these latter effects and generalized it, ignoring the unimportant distinction between vapor and gas.

* Contribution No. 242.

² Dalton, *Nicholson's Journ. Science* 5, 241 (1801).

³ Thus the equivalent of proposition (2) below is given by the *Encyclopedia Britannica*, Ed. 14, 6, 995; 13, 389 (1929), by Schaefer, *Einführung in die theoretische Physik*, II, 92, Berlin and Leipzig, 1929, and in a large number of texts on physical chemistry. No text has been found which shows an influence of Gibbs' formulation.

⁴ As in elementary texts on physics, following Ganot, *Traité de Physique*, Ganot, Paris, 1872.

He derived as a consequence of his formulation a series of propositions and pointed out that they, as well as the original formulation, are consistent and possible for gases obeying when pure any equations of state whatever. These propositions are involved in one extraordinarily condensed statement (page 157, just below equation 283). They may be stated as follows.⁵ 1. The concentration⁶ of any gas in a mixture is the same at equilibrium on either side of a membrane permeable to it alone. 2. The pressure of a gaseous mixture is equal to the sum of the individual gases as existing each by itself with the same temperature and volume as the mixture. (This is the common form of Dalton's law.) 3. Each of the quantities: the total energy, heat content, entropy, and $p-T$ and $v-T$ thermodynamic potentials (or free energies) equals the sum of the respective values for the individual gases as existing each by itself with the temperature and volume of the mixture. To these may be added another consequence,⁴ 4: The heat capacity at constant volume of a mixture of gases equals the sum of the heat capacities of the individual gases as existing each by itself at the temperature and volume of the mixture.

For let U be the energy and C the constant-volume heat capacity of the mixture, and U_{iv} and C_{iv} be the energy and heat capacity of any gas (i) of the mixture but in the pure state at the temperature T and the volume V of the mixture.⁷ Then Gibbs shows that $U = \sum_i U_{iv}$, from which $(\partial u / \partial T)_v = \sum_i (\partial u_{iv} / \partial T)_v$. Since $(\partial u / \partial T)_v = C$ we have therefore that $C = \sum_i C_{iv}$.

Gibbs states only one proposition in the nature of a converse, namely: 5. If the total $v-T$ thermodynamic potential (or Helmholtz free energy) of the mixture is equal to the sum of the values of this function for the several component gases existing each by itself in the same quantity as in the gas mixture and with its temperature and volume, then the Gibbs-Dalton law and all its consequences must hold. Two other converse propositions (6 and 7) may be added.

6. If the concentration of each gas in a mixture is the same at equilibrium on either side of a membrane permeable to it alone, the Gibbs-Dalton law and its consequences must hold. Let n_1 be the number of moles (or grams) of gas 1 in the mixture, of which the volume is V , and the pressure p , and let n_{1e} , V_{1e} , and p_{1e} be the corresponding quantities for the pure gas 1 in such a state as to be in equilibrium with the mixture with respect to transfer of gas 1. p_{1e} will be hereafter called the equilibrium pressure, and n_{1e}/V_{1e} the equilibrium concentration. Then by hypothesis,

$$n_1/V = n_{1e}/V_{1e}. \quad (1)$$

Gibbs' equation 98 is

$$dp = (S/V)dT + (n_1/V)d\mu_1 + (n_2/V)d\mu_2 + \text{etc.} \quad (2)$$

⁵ With less elegance, and with some redundancy.

⁶ As in moles per liter, or grams per cc. Dalton uses "density, considered abstractly," and Gibbs, "separate density," or simply "density," for what is now called concentration.

⁷ Naturally also, the same mass of pure gas is considered as is present in the mixture. This is understood to be the case in any of the comparisons, as otherwise no comparison is possible.

By substitution,

$$dp = (S/V)dT + (n_{1e}/V_{1e})d\mu_1 + (n_{2e}/V_{2e})d\mu_2 + \text{etc.} \quad (3)$$

Applying equation 98 in succession to the pure gases 1, 2, etc., we have

$$n_{1e}/V_{1e} = (\partial p_{1e}/\partial \mu_1)_T, \quad n_{2e}/V_{2e} = (\partial p_{2e}/\partial \mu_2)_T, \text{ etc.} \quad (4)$$

By substitution we have at constant temperature

$$dp = (\partial p_{1e}/\partial \mu_1)_T d\mu_1 + (\partial p_{2e}/\partial \mu_2)_T d\mu_2 + \text{etc.} \quad (5)$$

Since each pure gas remains in equilibrium with the mixture, μ and $d\mu$ for any gas is the same in the mixture as for the pure gas. Therefore the last equation may be immediately integrated at constant temperature to

$$p = p_{1e} + p_{2e} + p_{3e} + \text{etc.} + f(T), \quad (6)$$

since each term like $(\partial p_{1e}/\partial \mu_1)_T d\mu_1$ is at constant temperature of the form $(dz/dx)dx$, the variables having been separated. But $f(T)$ must be zero, in order that the expression shall reduce to the identity $p = p_{1e}$ for the special case in which the mixture is replaced with pure gas 1. Evidently the following law is in all ways equivalent to the Gibbs-Dalton law; (1): The concentration of each gas in a mixture is the same at equilibrium on either side of a membrane permeable to it alone.⁸

It should be noted that proposition 2, which is the form of Dalton's law commonly taught in texts on physical chemistry, is a consequence of the Gibbs form, but is less inclusive, as it asserts nothing about equilibrium. We may now show, however, that: (7). If we assume that the Gibbs form is true in the limiting case of infinitely large volumes, then proposition 3 asserted for all pressures, requires the validity of the Gibbs form at all pressures. Let the pure gases be kept throughout the variations at the volume and temperature and in the quantities present in the mixture, and consider variations of V and of n_1, n_2 , etc. Let the pressure and potential of the pure gas 1 at the temperature and volume of the mixture be represented by p_{1v} and μ_{1v} and likewise for other species. Then proposition 2 may be written

$$p = \Sigma(p_{1v} + p_{2v} + \text{etc.}) \quad (7)$$

Then

$$(\partial p/\partial n_1)_{T,v,n} = (\partial/\partial n_1)_{T,v,n} \Sigma(p_{1v}) = (\partial p_{1v}/\partial n_1)_{T,v}. \quad (8)$$

But⁹

$$(\partial \mu_1/\partial V)_{T,n} = -(\partial p/\partial n_1)_{T,v,n} \text{ and } (\partial \mu_{1v}/\partial V)_{T,n_1} = -(\partial p_{1v}/\partial n_1)_{T,v} \quad (9)$$

⁸ The same is true of the proposition: (1a) There is equilibrium when the concentration of a gas is the same on either side of the semipermeable membrane, (the temperature being uniform). This is because Gibbs proves (reference 1, page 67) that equality of potentials and temperature is necessary and sufficient for equilibrium. But even without this, physical reasoning shows that there is no point in observing the logical distinction between (1) and (1a).

⁹ These equations result from cross differentiation of Gibbs' Eq. (88).

and therefore

$$(\partial\mu_1/\partial V)_{Tn} = (\partial\mu_{1e}/\partial V)_{Tn_1}. \quad (10)$$

Hence, since equilibrium is supposed at zero pressure when in equal volumes the numbers of moles of kind 1 are equal in the pure gas and in the mixture, these volumes may be equally reduced as much as we please without changing the numbers of moles; the potentials will change by the same amounts for the pure gas and the mixture, so that their differences will remain zero, and the system will remain in equilibrium. Hence $p_1 = p_{1e}$, and similarly $p_2 = p_{2e}$, etc., and therefore

$$p = \Sigma(p_{1e} + p_{2e} + \text{etc.}) \quad (11)$$

But we believe that the Gibbs-Dalton law holds at zero pressure. When therefore we are interested solely in testing hypothesis or law by means of data, and not at all in developing or presenting a logical system, we may regard the simple additivity of pressures, as expressed in the common form of Dalton's law (proposition 2) as equivalent to the Gibbs formulation.

The theoretical treatment is incomplete if we omit to consider the form in which Dalton's law has frequently been used by specialists interpreting data. This is; (8) the equilibrium pressure of any gas in a mixture equals the total pressure of the mixture times its mole fraction in the mixture, or

$$p_{ie} = p(n_i/\Sigma_i n_i) = px_i, \quad (12)$$

where n_i is necessarily in moles rather than grams, and x_i is the mole fraction. When we come to examine the applicability of the Gibbs-Dalton law we should compare any success obtained with that obtained by the use of this form, which will be called Dalton's law in the ideal gas form.

Lurie and Gillespie¹⁰ pointed out that this form of Dalton's law contains the laws of Boyle and Avogadro. As their proof was incomplete in form, a complete proof is herewith given. Granted that $p_{ie} = px_i$ for every gas in a gas mixture. Then obviously $p = \Sigma_i px_i = \Sigma_i p_{ie}$, from which, according to the proof given by Gibbs, the concentration of any gas in the mixture, as n_i/V , equals the concentration of the pure gas when under its equilibrium pressure, as n_{ie}/V_{ie} . We have then

$$p_{1e} = px_1 = pn_1/\Sigma_i n_i \quad (13)$$

and

$$V_{1e}/n_{1e} = V/n_1 \quad (14)$$

From which,

$$p_{1e}V_{1e}/n_{1e} = pV/\Sigma_i n_i \quad (15)$$

Similarly

$$p_{2e}V_{2e}/n_{2e} = pV/\Sigma_i n_i \quad (16)$$

¹⁰ Lurie and Gillespie, Journ. Amer. Chem. Soc. 49, 1146 (1927).

Hence

$$p_{1e}V_{1e}/n_{1e} = p_{2e}V_{2e}/n_{2e}. \quad (17)$$

These equations must hold for equilibrium variations of the variables. Among the variables T , p , μ_1 , μ_2 , \dots , etc., only one relation (the fundamental equation) exists. Hence a variation in μ_1 is possible at constant μ_2 , μ_3 , etc., and T . Therefore at constant temperature a variation of p_{1e} is possible at constant p_{2e} , and constancy of p_{2e} requires at constant temperature a constant concentration n_{2e}/V_{2e} . Hence $p_{1e}V_{1e}/n_{1e}$ is a constant during variations of p_{1e} and if n_{1e} is arbitrarily held constant, pV is constant. This is Boyle's law. Furthermore, the constant $p_{1e}V_{1e}/n_{1e}$ is evidently independent in magnitude of the character of gas 1, and would be the same for some other gas. Hence this equation includes Avogadro's law, that n is the same for any gas when p and V are the same. If, also, these relations hold at any constant temperature, the expansions of the different gases must be alike. Hence this form of Dalton's law contains all of the laws of ideal gases except those relating to the energy (such as $(\partial u/\partial V)_T = 0$, or that pV is proportional to *thermodynamic* temperature), and, in the lack of a conventional name, may well be called Dalton's law in the ideal gas form.

The rule of Amagat,¹¹ that the volume of a gaseous mixture equals the sum of the volumes of the individual gases as existing each by itself at the temperature and (total) pressure of the mixture, is not here regarded as a form of Dalton's law.¹² It is analogous to the law of additive pressures (proposition 2) in many ways. Thus the fugacity rule of Lewis and Randall¹³ bears to this rule a relation similar to that existing between the Gibbs-Dalton law and the additivity of pressures. This fugacity rule, when the variable is changed from fugacity to chemical potential, states that the difference between the chemical potential of a gas in equilibrium with a mixture and the potential it would have at the temperature and pressure of the mixture is the same as for a system of ideal gases, i.e., $RT \ln x$. According to the Gibbs-Dalton law the difference between the potential of a gas in equilibrium with a mixture and the potential it would have at the temperature and volume of the mixture is the same as for a system of ideal gases, i.e., zero. As stated by Lewis and Randall, their rule implies the additivity (at constant temperature and pressure) of volume and heat content. As shown by the author,¹⁴ the additivity of volumes is enough, together with suitable assumptions relating to the gases at zero pressure (which may be, for example, that the rule is exact at zero pressure) to establish the rule. Furthermore, the rule makes the partial molal volume \bar{V}_1 of a gas in a mixture equal to the molal volume V_{1p} of the pure gas at the temperature and

¹¹ Amagat, Ann. chim. phys. [5] 19, 384 (1880); Compt. rend. 127, 88 (1898).

¹² Fortunately very few authors have called it Dalton's law. Curiously, this form was actually stated by Dalton, whereas the common form was not stated by him, though it was used. The two forms are naturally equivalent when ideal gases are under consideration, as was the case in all of Dalton's considerations.

¹³ Lewis and Randall, Thermodynamics, McGraw-Hill Book Co. Inc., New York, 1923.

¹⁴ Gillespie, Journ. Amer. Chem. Soc. 47, 305 (1925).

pressure of the mixture; that is, $\bar{V}_1 - V_{1p}$ and its temperature and pressure derivatives become zero. Examination now of equations 6a, 7, 10, and 14 of a previous paper¹⁵ will show that this leads to the following consequences. The difference between any one of the functions: the total energy, heat content, entropy, and $p-T$ and $v-T$ thermodynamic potentials for the mixture, as against the sum of the corresponding values of any function for the individual gases taken at the temperature and pressure of the mixture, must have at all pressures the same value as at zero pressure. This difference is zero for the energy and heat content, but is expressed in terms involving $\log x$ in the case of the entropy and the two thermodynamic potentials, whereas according to the Gibbs-Dalton law the corresponding differences (taken at the temperature and volume of the mixture) are all zero. Finally, the rule makes the heat capacities at constant pressure additive, since these are the temperature derivatives at constant pressure of the additive heat contents.

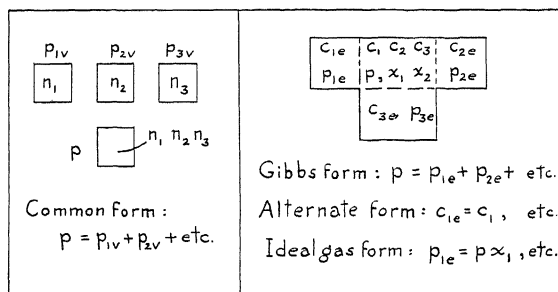

Fig. 1. Illustrating various forms of Dalton's law.

In Fig. 1 some of the principal relations among the forms of Dalton's law are shown and the use of symbols illustrated.

2. COMPARISON OF THE GIBBS-DALTON LAW WITH DATA

Figure 2 (L-G) Data of Lurie and Gillespie. These data are the values of p and x_1 for mixtures of ammonia (subscript 1) and nitrogen (subscript 2) at 45° observed for corresponding values of p_{1e} , which is the vapor pressure of barium chloride octammine corrected for the total pressure. In the former comparison, the quantities calculated and observed were the equilibrium pressure p_{1e} . A more direct comparison is here given between the calculated and observed values of x_1 . In the present calculations from the Gibbs-Dalton law the Beattie-Bridgeman equations of state¹⁶ for both gases were used. Fig. 2 shows the observed minus the calculated mole percent ammonia in percent deviation of the observed value. The percentage deviations are shown for the Gibbs-Dalton law (circles, solid line) and for Dalton's law in the ideal gas form (squares, broken line).

values of p_{1e} , the vapor pressure of liquid ammonia corrected for the lowering due to dissolved gas and the raising due to the increased total pressure. The temperatures are from -20° to 20°C . The thermodynamic calculations

Fig. 3. Errors of the Gibbs-Dalton law.

were performed by Cupples¹⁸ for the purpose of determining the existence of a true "solvent action." Previous authors had ascribed deviations from

¹⁷ Larson and Black, *Journ. Amer. Chem. Soc.* **47**, 1015 (1925).

Dalton's law in the ideal gas form to the existence of a solvent action. The solvent action, as defined by him, is zero when the concentration of gas is the same at equilibrium on either side of an appropriate membrane. From the theoretical part above, it is evident that such calculations afford a direct test of the Gibbs-Dalton law. These calculations extend to 600 atmospheres, at which point the vapor pressure has been corrected to double its original value for the increase in total pressure. In applying this correction, the equation of state of ammonia has to be extrapolated well into the region of supersaturation and it is difficult or impossible at present to determine just how much reliance may be put on the calculations at the higher pressures. Consequently, more emphasis will here be put on the trends at the lower pressures. Figure 2 shows the percentage deviation, observed minus calculated mole percent ammonia, the percentage being based on the observed. As in the previous figure the deviation must be zero when the total pressure is equal to the normal vapor pressure, the mole fraction of ammonia then being unity. In Fig. 2 the points are connected by straight lines in order not to prejudice the smoothing. In Fig. 3 smoothed curves are drawn (solid lines near the circles) for the Gibbs-Dalton law, and also for the ideal gas form (broken lines and squares). The lines of zero deviation are heavy, and the scale divisions of ordinates are 10 percent in all cases.

Examination of the figures shows that the Gibbs-Dalton law fails to fit the data, especially at the lower pressures, where the calculations are most certain. It is true that in Fig. 2 at 10 and 20° the deviations are substantially zero for 50 and 100 atmospheres, and if only these two isotherms were given, one might conclude that the deviations appear to be zero, perhaps even above 300 atmospheres. This would involve the ignoring of the 300 atmosphere points. Taking the picture as a whole there appears to be no doubt that it is rather the 50 and 100 atmosphere points which are in error, and that the family of curves should be drawn with maxima, which move towards higher pressure at higher temperature. The deviations of the Gibbs-Dalton law are in all cases smaller than those of the ideal gas form, but the difference is not in most cases impressive. There is a hint that the contrary may be the case at sufficiently high pressures.

The existence of maxima in the curves seems consistent with the findings of Masson and Dolley¹⁹ in the cases of mixtures of ethylene with oxygen; here the deviations from the law of additive pressures also increase at first with pressure and pass through a maximum, in some cases changing sign at the highest pressures. In general it appears that the maximum occurs at lower pressures, the less perfect the gas mixture.

The foregoing conclusions, as respects the data of Larson and Black, are not the same as those drawn by Cupples. The principal reason for this appears to be that his plot, based on different variables, does not show the zero deviations which must occur at all temperatures in the limiting case in which the gas phase is pure ammonia.

3. APPLICATION

By virtue of certain assumptions as to the properties of gaseous mixtures and pure gases at infinitely low pressures, which may for present purposes be freely expressed as follows: the behavior of real gases approaches that of ideal gases at zero pressure,—it is possible to correlate equilibrium data in a purely thermodynamic manner with pressure data for the pure gases in question and for mixtures of them, together with specific heats also, if temperature correlation is included. To avoid the necessity of data on gas mixtures, some assumption may be made regarding the pressures or volumes of gaseous mixtures, compared with those of their constituent pure gases. Only three such assumptions are to be found as the basis of methods which have received any degree of attention.²⁰ They are (1) the additivity of pressures or the Gibbs-Dalton law, (2) the additivity of volumes or the Lewis and Randall rule of fugacity, and (3) the additivity of equation of state constants, usually described in publications from this laboratory as linear combination of constants.²¹

Examination of the pressure data of mixtures, as well as application to equilibria, has shown that the third method is in general more accurate than the other two methods.²² Nevertheless the former two may be of service in special instances, due to the fact that in certain types of calculation they will require much less computation than the third method.

For calculations of the effect of pressure upon equilibrium constants the Lewis and Randall rule is especially adapted. It fits the Haber equilibrium data up to about 100 atmospheres.²³ A mass action equation may readily be derived from the Gibbs-Dalton law and the individual equations of state, but it has the disadvantage that the expression for the effect of pressure on the equilibrium constant involves terms in mole fractions, which would greatly complicate the calculation. Neither method can be trusted to give accurately the effect of varying mole fraction on the equilibrium constant.

For the calculation of the concentrations of a gaseous mixture which is in equilibrium with a liquid or other phase, or even for the calculation of the mole fractions of such a mixture, the Gibbs-Dalton law is especially adapted. It has an important advantage over the Lewis and Randall rule, that the

²⁰ We omit here the usual Dalton law in the ideal gas form, as its use is inconsistent with any equation of state but that of Boyle.

²¹ *I. e.*, linear in all the constants which are of the first power in the volume and in the square root of the cohesive pressure A constant, which root is of the first power.

²² Evidence in support of it may be marshalled from the following papers. Lurie and Gillespie reference 10; Keyes and Burks, *Journ. Amer. Chem. Soc.* **50**, 1100 (1928); Beattie, *Journ. Amer. Chem. Soc.* **51**, 19 (1929); Gillespie, *Phys. Rev.* **34**, 352 (1929); Beattie and Ikeshara, "An Equation of State for Gas Mixtures. II. A Study of the Methods of Combination of the Constants of the Beattie-Bridgeman Equation of State." (to be published soon); and Gillespie and Beattie, "Correlation of the Haber Equilibrium Data with Compressibilities and Specific Heats of the Pure Gases by Means of a Rational Mass Action Equation" (to be published soon).

²³ Gillespie, *Journ. Amer. Chem. Soc.* **48**, 28 (1926).

equations of state do not need such severe extrapolation into the region of supersaturation. Thus for the data of Lurie and Gillespie at a total pressure of 60 atmospheres, the equation of state needs extrapolation from 7.1 to 60 atmospheres in the one case and from 7.1 to but about 7.4 atmospheres in the other.

An outline of the calculations from the Gibbs-Dalton law follows.

Let $p_1 = f_1(T, n_1/V)$, $p_2 = f_2(T, n_2/V)$, etc., be the equations of state of the several gases. Then $p = f_1(T, n_1/V) + f_2(T, n_2/V) + \text{etc.}$, where p and V are the pressure and volume of the mixture and n_1, n_2 , etc., are the numbers of moles in the mixture.

Solution for the equilibrium pressure, p_{1e} , of a gas (1) in the mixture from known values of p and the mole fractions x_1, x_2 , etc., proceeds by putting $\sum_i n_i = 1$ and finding by trial a value of V which will satisfy

$$p = f_1(T, x_1/V) + f_2(T, x_2/V) + \text{etc.} \quad (18)$$

When the computed pressure finally checks the observed pressure, the final values of $f_1(T, x_1/V)$, $f_2(T, x_2/V)$, etc., are the calculated equilibrium pressures. Any equilibrium pressure is the pressure of the pure gas that would be in equilibrium with the mixture; and, when a liquid is in equilibrium with the mixture, the equilibrium pressure is equal to the vapor pressure of the liquid, corrected by means of Poynting's equation for the increased total pressure, and by means of Raoult's law for the solubility of the inert gases in the liquid.²⁴

Solution for the mole fractions from known equilibrium pressures and the known pressure of the mixture proceeds as follows. Calculate n_1/V from the equilibrium pressure p_{1e} of gas 1 by means of the equation of state:

$$p_{1e} = f_1(T, n_1/V) \quad (19)$$

by successive approximations. If the mixture is binary, $p_{2e} = p - p_{1e}$, and n_2/V may be similarly calculated from the equation of state of gas 2. If the mixture is binary with respect to a gas (1) like ammonia and a mixture (2) of gases in constant mole ratio, such as a 3:1 hydrogen-nitrogen mixture, treat this constant mixture (which will not change greatly through differential solubility) as a pure gas whose constants are obtained by "linear combination of constants,"^{21,22} unless the equation for the mixture has already been determined. If the mixture is ternary or more complicated, another equilibrium pressure must obviously be known for each added constituent. When in any case the values of n_1/V , n_2/V , etc. have been calculated, any mole fraction is immediately found from the relation

$$x_i = \frac{n_i/V}{\sum_i (n_i/V)} \quad (20)$$

In order to avoid some of the successive approximations, the volume equation of Beattie²⁵ may be used. The calculations may also be done

²⁴ This latter correction was found small by Larson and Black (17).

²⁵ $(V/n_i) = f_i(T, p)$, Beattie, Proc. Nat. Acad. Sci. 16, 14 (1930).

throughout by means of graphs. It is of course unnecessary to introduce fugacities²⁶ unless some of the experimental information is found expressed in terms of them.

4. THE SIGN OF THE ERRORS IN THE APPLICATION

At low pressures the partial volume \bar{V}_1 of a gas in a mixture is found in general to be greater than the molal volume V_{1p} of the pure gas at the pressure and temperature of the mixture.²⁷ From an equation previously given²³

$$RT \ln f_1 = \int_0^p (\bar{V}_1 - RT/p) dp + RT \ln p x_1 \quad (21)$$

the signs of the errors to be expected of the Lewis and Randall rule at low pressures can readily be determined. For according to the rule, $\bar{V}_1 = V_{1p}$, hence in applying the rule a value of the integral is virtually used which is too small algebraically. Hence the mole fraction x_1 calculated by the rule from a known fugacity f_1 (determined from the vapor pressure, of which it is an increasing function) will come out too large.

In the case of the Gibbs-Dalton law, no special study has been made of the analogous quantity $(\partial p / \partial n_1)$. It is worthy of notice, however, that the mole fractions calculated from the vapor pressures are too low at the lower pressures in the cases examined above. Thus, at least in these cases, the true value evidently lies between those given by the two approximate methods.

A RATIONAL BASIS FOR THE THERMODYNAMIC TREATMENT OF REAL GASES AND MIXTURES OF REAL GASES

BY JAMES A. BEATTIE

RESEARCH LABORATORY OF PHYSICAL CHEMISTRY, MASSACHUSETTS

INSTITUTE OF TECHNOLOGY.*

(Received May 19, 1930)

ABSTRACT

From the general laws of thermodynamics and two isothermal assumptions, one of which states that at constant temperature the energy of a pure gas approaches a function of the temperature in the following manner:

$$U_1 = f_1(T) + \zeta_1 p$$

and the other that at constant temperature and composition the ratio of the equilibrium pressure of a gas in a mixture to the product of the mole fraction of the gas in the mixture multiplied by the total pressure of the mixture approaches unity in the following manner:

$$\frac{p_{ei}}{p x_i} = 1 + \xi_i p$$

where ζ_i and ξ_i are bounded parameters, it has been shown that the following relations hold for real gases or mixtures of real gases at infinitely low pressures:

(a). The ratio of the equilibrium pressure of a gas to the product of its mole fraction in the mixture multiplied by the total pressure of the mixture is unity.

(b). The ratio of the equilibrium concentration of a gas to its concentration in the mixture is unity.

(c). The ratio of the sum of the equilibrium pressures (or equilibrium concentrations) of the component gases to the total pressure (or concentration) of the gas mixture is unity.

(d). The entropy, energy, heat content, thermodynamic potentials and heat capacities at constant volume and at constant pressure of a mixture of gases are equal respectively to the sums of the entropies, energies, heat contents, thermodynamic potentials and heat capacities of the component gases existing each by itself with the same value of its volume, temperature and chemical potential as in the mixture. The above statement holds when the component gases exist each by itself with the same value of its volume and temperature as in the gas mixture and with the ratio of its concentration to its concentration in the gas mixture equal to unity.

(e). The energy, heat content and heat capacities of pure gases and of gas mixtures of constant composition are functions of the temperature.

(f). The difference between the heat capacity at constant pressure and that at constant volume of a pure gas or of a gas mixture is equal to the product of the total number of moles present multiplied by the gas constant R .

(g). The pressure-volume product for a pure gas or for a gas mixture is equal to the product of the total number of moles present multiplied by RT where R is a universal constant and T the Kelvin temperature.

1. INTRODUCTION

IN ORDER to give a general thermodynamic treatment for mixtures of real gases comparable to that given by Gibbs¹ for mixtures of ideal gases it is necessary to make several assumptions. Gillespie² has shown that a general relation for the isothermal variation of the mass action function K_p (which represents chemical equilibria in gaseous systems) can be derived from general thermodynamic considerations together with the one assumption: At very low pressures the "equilibrium pressure" of each gas in a mixture is equal to the product of the mole fraction of that gas in the mixture multiplied by the total pressure of the mixture. It has also been shown³ that relations for the variation of the thermodynamic properties of gas mixtures with temperature and pressure (or volume) can be derived from the above assumption and one other: At very low pressures the energy of a mixture of gases is equal to the sum of the energies of the component gases existing each by itself at the temperature and in the total volume of the mixture. Besides these two assumptions for gas mixtures, there was used the assumption that at very low pressures the pressure of a pure gas is equal to nRT/V .

De Donder⁴ has given relations for some of the thermodynamic properties of gas mixtures on the assumption that, as the pressure on the mixture is decreased at constant temperature, certain properties of the gas mixture approach those of mixtures of ideal gases. Keyes⁵ has given an equation for the mass action function K_p by use of the kinetic considerations from which the Keyes⁶ equation of state was derived.

It is to be noted that the assumptions which it has been found necessary to make relate to the thermodynamic properties of gaseous systems under low pressures. In the following treatment it is shown that all of the necessary relations for the treatment of real gases and mixtures of real gases can be derived from two assumptions, each of which are for isothermal conditions.

We shall consider two pressure regions:

(1) *Low pressures*, at which for all practical purposes terms of the order of p^2 can be neglected in comparison with unity, or with terms of the order of p .

(2) *Very low pressures*, at which for all practical purposes terms of the order of p can be neglected in comparison with unity. An asterisk placed after a thermodynamic quantity is used to denote the values which the quantity in question assumes in the region of very low pressures.

From an experimental standpoint one atmosphere may be considered a "low pressure" for the permanent gases at room temperature; and one centimeter of mercury, a "very low pressure."

Throughout the present treatment we shall use the greek letters α , β , ζ , η , κ and ξ to denote bounded parameters; that is, parameters whose numerical magnitudes do not exceed an assignable upper limit. When occurring with the subscript 1, they refer to pure gases without reference to any gas mixture, and vary with the temperature; when used without subscripts or with the subscript i they refer to a mixture of gases and vary with the temperature and the composition of the mixture.

2. THE SYSTEM UNDER CONSIDERATION

Let p , V , T be the total pressure, total volume, Kelvin temperature and U , S , H , F_{VT} , F_{pT} , C_V , C_p be the total energy, entropy, heat content, thermodynamic potentials and heat capacities of a mixture of real gases consisting of n_1 , n_2 , \dots moles of the Gases 1, 2, \dots whose chemical potentials in the mixture are μ_1 , μ_2 , \dots . Let $C = \Sigma n_i/V$ be the concentration of the mixture; $C_i = n_i/V$ be the concentration of Gas i in the mixture; and $x_i = n_i/\Sigma n_i$ be the mole fraction of Gas i in the mixture.

Let p_{ei} , U_{ei} , S_{ei} , H_{ei} , $F_{VT_{ei}}$, $F_{pT_{ei}}$, $C_{V_{ei}}$, $C_{p_{ei}}$ be the pressure, energy, entropy, heat content, thermodynamic potentials, and heat capacities respectively of n_{ei} moles of the pure Gas i ($i=1, 2, \dots$) existing by itself in the total volume V , at the temperature T and with the chemical potential μ_i ; the quantities V , T and μ_i having identically the same values that apply to the gas mixture. Let $C_{ei} = n_{ei}/V$ be the concentration of the pure Gas i .

It is evident that the pure Gas i is in equilibrium with the gas mixture with respect to the isothermal transfer of Gas i from the vessel containing the pure gas to that containing the mixture or from the mixture to the pure gas, the chemical potential of the pure Gas i being kept equal to that of Gas i in the mixture throughout the process; that is, each gas would be in equilibrium with the gas mixture through a semipermeable membrane which permits only that gas to pass through. Hence the quantities with the subscript e will be called the "equilibrium" quantities.

Thermodynamic quantities with the subscript 1 refer to pure gases which are considered without relation to any gas mixture.

3. THE ASSUMPTIONS

Assumption 1: At all temperatures⁷ the energy of a real gas differs from a function of the temperature by a quantity which, at constant temperature, approaches zero with the pressure, p in the manner that $\zeta_1 p$ approaches zero with the pressure where ζ_1 and its derivative are bounded.

Assumption 2: At all temperatures⁷ the ratio of the equilibrium pressure of each gas in a mixture to the product of the mole fraction of that gas in the mixture multiplied by the total pressure p of the mixture differs from unity by a quantity which, at constant temperature and composition, approaches zero with the total pressure in the manner that $\xi_i p$ approaches zero with the total pressure, where ξ_i and its derivatives are bounded.

⁷ This means, of course, for the temperature range for which the resulting thermodynamic relations are to be used. The region in the immediate neighborhood of 0°K is to be excluded.

Thus for all temperatures we may write for low pressures:

$$U_1 = f_1(T) + \zeta_1 p \quad (1)$$

$$\frac{p_{ei}}{p x_i} = 1 + \xi_i p \quad (i = 1, 2, \dots). \quad (2)$$

In Eq. (1) U_1 is the energy of n_1 moles of any pure Gas 1, T the Kelvin temperature and p the pressure of the gas; the function $f_1(T)$ is a characteristic function of the temperature for each gas, and the parameter ζ_1 varies with the temperature. In Eq. (2) p_{ei} is the equilibrium pressure of Gas i , x_i its mole fraction in the mixture and p the total pressure of the mixture; the parameter ξ_i varies with the temperature and composition of the mixture.

At very low pressures (1) and (2) become:

$$U_1^* = f_1(T) \quad (3)$$

$$\left(\frac{p_{ei}}{p x_i}\right)^* = 1 \quad (i = 1, 2, \dots). \quad (4)$$

Thus:

At very low pressures the energy of a pure gas is a function of the temperature alone.

At very low pressures the ratio of the equilibrium pressure of a gas to the product of the mole fraction of the gas in the mixture multiplied by the total pressure of the mixture is unity.

4. THE EQUILIBRIUM CONCENTRATION

For the gas mixture we may write the fundamental equation:

$$V dp = S dT + n_1 d\mu_1 + n_2 d\mu_2 + \dots \quad (5)$$

and for each pure gas there is a relation of the type:

$$V dp_{ei} = S_{ei} dT + n_{ei} d\mu_i \quad (i = 1, 2, \dots) \quad (6)$$

where V , dT , $d\mu_1$, $d\mu_2$, \dots have identically the same values in (5) and (6). From (5) we see that:

$$\left(\frac{dp}{d\mu_i}\right)_{T, \mu} = \frac{n_i}{V}; \quad \left(\frac{dp}{dT}\right)_\mu = \frac{S}{V} \quad (i = 1, 2, \dots) \quad (7)$$

and from (6):

$$\left(\frac{dp_{ei}}{d\mu_i}\right)_T = \frac{n_{ei}}{V}; \quad \left(\frac{dp_{ei}}{dT}\right)_{\mu_i} = \frac{S_{ei}}{V} \quad (i = 1, 2, \dots) \quad (8)$$

The subscript μ to a partial derivative indicates that during the differentiation all of the μ 's are held constant, unless the differentiation is with respect to one of the μ 's in which case all of the other μ 's are held constant.

Eq. (2) can be written:

$$p_{ei} = p x_i (1 + \xi_i p) \quad (i = 1, 2, \dots) \quad (9)$$

Adding the equilibrium pressures for all of the gases in the mixture and placing $\sum x_i = 1$, we obtain:

$$\sum p_{ei} = p(1 + \xi p) \quad (10)$$

where ξ has been written for $\sum x_i \xi_i$. Differentiation of (10) successively with respect to μ_1, μ_2, \dots gives the relations:

$$\left(\frac{dp_{ei}}{d\mu_i} \right)_T = \left(\frac{dp}{d\mu_i} \right)_{T,\mu} (1 + 2\xi p) + p^2 \left(\frac{d\xi}{d\mu_i} \right)_{T,\mu} \quad (i = 1, 2, \dots) \quad (11)$$

Since:

$$\left(\frac{d\xi}{d\mu_i} \right)_{T,\mu} = \left(\frac{dp}{d\mu_i} \right)_{T,\mu} \left(\frac{d\xi}{dp} \right)_{T,\mu_2,\mu_3,\dots} \quad (i = 1, 2, \dots) \quad (12)$$

Eq. (11) may be written:

$$\left(\frac{dp_{ei}}{d\mu_i} \right)_T = \left(\frac{dp}{d\mu_i} \right)_{T,\mu} \left[1 + 2\xi p + p^2 \left(\frac{d\xi}{dp} \right)_{T,\mu_2,\mu_3,\dots} \right] \quad (i = 1, 2, \dots) \quad (13)$$

By Assumption 2 the partial derivative in the last term of (13) is bounded, and hence this term is of higher order than $2\xi p$. Replacing the partial derivatives of (13) by use of the relations (7) and (8) we obtain for low pressures the equations:

$$\frac{n_{ei}}{V} = \frac{n_i}{V} (1 + 2\xi p) \quad (i = 1, 2, \dots) \quad (14)$$

In terms of concentrations (14) becomes:

$$\frac{C_{ei}}{C_i} = 1 + 2\xi p \quad (i = 1, 2, \dots) \quad (15)$$

and at very low pressures:

$$\left(\frac{C_{ei}}{C_i} \right)^* = 1 \quad (i = 1, 2, \dots) \quad (16)$$

At very low pressures the ratio of the equilibrium concentration of a gas to its concentration in the gas mixture is unity.

Eq. (16) may be written in a form corresponding more closely to (4):

$$\left(\frac{C_{ei}}{C x_i} \right)^* = 1 \quad (i = 1, 2, \dots) \quad (17)$$

5. THE LAWS OF BOYLE AND AVOGADRO

Lurie and Gillespie⁸ have shown that if Eq. (4) holds at all pressures, then the gases obey the laws of Boyle and of Avogadro. Similar results may be obtained for real gases at very low pressures from the Assumption 2. When the relation (9) for each gas is divided by the corresponding relation (14), we obtain:

$$\frac{p_{ei}V}{n_{ei}} \frac{1}{1 + \xi_i p} = \frac{pV}{\Sigma n_i} \frac{1}{1 + 2\xi p} \quad (i = 1, 2, \dots) \quad (18)$$

Consider that n_{e1}, n_{e2}, \dots moles of the pure gases 1, 2, \dots and Σn_i moles of the gas mixture are placed in separate compartments each of volume V and at temperature T , and that the chemical potential of each of the pure gases has the same value during all variations as that which it has in the gas mixture. Let T, μ_1, μ_2, \dots be taken as the independent variables as in Eqs. (5) and (6). In the following discussion all variations are made at constant temperature. With μ_1 held constant both for the pure gas and the gas mixture we can vary μ_2, μ_3, \dots thus causing the pressures and concentrations of the Gases 2, 3, \dots and of the gas mixture to vary. From (6) we see that the first term of (18) for Gas 1 cannot vary except through the factor $(1 + \xi_1 p)$, but the effect of this variation can be made as small as desired by carrying out the whole process at sufficiently low pressures. At very low pressures the first term of (18) for Gas 1 may be considered constant during the given variations and hence each of the other terms must have remained constant during the variations. But Gas 2 or any other of the gases could just as well have been chosen as the one whose chemical potential was held constant. Hence for all isothermal variations of the chemical potentials at very low pressures:

$$\left(\frac{p_1 V_1}{n_1}\right)^* = \left(\frac{p_2 V_2}{n_2}\right)^* = \dots = \left(\frac{pV}{\Sigma n_i}\right)^* = \text{constant} = F(T). \quad (19)$$

The terms of (19) are each individually constant at constant temperature for gases or gas mixtures each confined in a cylinder. Hence the quantities $p_1^*, (V_1/n_1)^*, p_2^*, (V_2/n_2)^*, \dots$ which refer to the Gases 1, 2, \dots are no longer necessarily equilibrium values. The temperature function $F(T)$ is the same for all of the gases. For very low pressures we may write:

$$\frac{(pV)^*}{n_1} = F(T) \quad (20)$$

for any pure real gas; and:

$$\frac{(pV)^*}{\Sigma n_i} = F(T) \quad (21)$$

⁸ Lurie and Gillespie, Jour. Amer. Chem. Soc. **49**, 1146 (1927), See also Gillespie, Phys. Rev., **36**, 121 (1930).

for any mixture of real gases. Hence:

At very low pressures the laws of Boyle and Avogadro hold for all real gases and mixtures of real gases.

At very low pressures the ratio of the pressure to the concentration is the same function of the temperature for all real gases and mixtures of real gases.

Now

$$\left(\frac{dU}{dV}\right)_T = T\left(\frac{dp}{dT}\right)_V - p \quad (22)$$

and from this relation together with (1) and (20) it is evident that at low pressures:

$$\frac{pV}{n_1} = F(T) + \beta_1 p \quad (23)$$

or to the same degree of approximation:

$$\frac{pV}{n_1} = F(T) \left(1 + \frac{n_1 \beta_1}{V}\right) \quad (24)$$

where the subscript 1 refers to any pure gas and the parameter β_1 varies with the temperature. Moreover for gas mixtures at low pressures we can evidently write:

$$\frac{pV}{\sum n_i} = F(T) + \beta p \quad (25)$$

or to the same degree of approximation:

$$\frac{pV}{\sum n_i} = F(T) \left(1 + \frac{\sum (n_i) \beta}{V}\right) \quad (26)$$

where the parameter β varies with the temperature and composition of the mixture.

6. ADDITIVITY OF CERTAIN THERMODYNAMIC FUNCTIONS

Gibbs⁹ has shown that if the pressure of a mixture of gases is equal to the sum of the equilibrium pressures of the component gases then certain thermodynamic quantities are "additive." We can derive similar relations for real gases at very low pressures from the Assumption 2.

Differentiating (10) with respect to the temperature at constant μ_1, μ_2, \dots we obtain:

$$\sum \left(\frac{dp_{ei}}{dT}\right)_{\mu_i} = \left(\frac{dp}{dT}\right)_{\mu} (1 + 2\xi p) + p^2 \left(\frac{d\xi}{dT}\right)_{\mu} \quad (27)$$

⁹ Gibbs, Scientific Papers; Vol. I, p. 157.

which may be written:

$$\Sigma V \left(\frac{dp_{ei}}{dT} \right)_{\mu_i} = V \left(\frac{dp}{dT} \right)_{\mu} \left[1 + 2\xi p + p^2 \left(\frac{d\xi}{dp} \right)_{\mu} \right]. \quad (28)$$

The last term is of higher order than $2\xi p$ and may be neglected. Substitution from (7) and (8) into (28), gives for low pressures the result:

$$\Sigma S_{ei} = S(1 + 2\xi p). \quad (29)$$

The energy of the mixture is given by the relation:

$$U = TS - pV + \mu_1 n_1 + \mu_2 n_2 + \dots \quad (30)$$

and for each pure gas there is a relation of the type:

$$U_{ei} = TS_{ei} - p_{ei}V + \mu_i n_{ei} \quad (i = 1, 2, \dots) \quad (31)$$

Adding the Eqs. (31) for all of the gases composing the mixture and making use of the relations (10), (14) and (29), we obtain:

$$\Sigma U_{ei} = TS(1 + 2\xi p) - pV(1 + \xi p) + \Sigma(\mu_i n_i)(1 + 2\xi p) \quad (32)$$

Hence at low pressures:

$$\Sigma U_{ei} = U(1 + 2\xi p) + pV\xi p. \quad (33)$$

From the definitions:

$$H = U + pV \quad (34)$$

$$F_{VT} = U - TS \quad (35)$$

$$F_{pT} = U - TS + pV \quad (36)$$

and the relations already given, we find that at low pressures:

$$\Sigma H_{ei} = H(1 + 2\xi p) \quad (37)$$

$$\Sigma F_{VT_{ei}} = F_{VT}(1 + 2\xi p) + pV\xi p \quad (38)$$

$$\Sigma F_{pT_{ei}} = F_{pT}(1 + 2\xi p). \quad (39)$$

From (25) we note that at low pressures the quantity pV is bounded. By use of the relations already given and the first and second law equation, it can readily be shown that as the pressure on a gaseous system is isothermally reduced, the energy and heat content are bounded, and that the entropy and thermodynamic potentials approach plus or minus infinity in the same manner as $\pm \ln p$. But:

$$\lim_{p \rightarrow 0} p \ln p = 0$$

and hence at very low pressures:

$$\Sigma S_{ei}^* = S^* \quad (40)$$

$$\Sigma U_{ei}^* = U^* \quad (41)$$

$$\Sigma H_{ei}^* = H^* \quad (42)$$

$$\Sigma F_{VT\ ei}^* = F_{VT}^* \quad (43)$$

$$\Sigma F_{pT\ ei}^* = F_{pT}^* \quad (44)$$

At very low pressures the entropy, energy, heat content, and thermodynamic potentials of a mixture of real gases are equal respectively to the sum of the entropies, energies, heat contents, and thermodynamic potentials of the component gases existing each by itself with the same value of its volume, temperature and chemical potential as in the gas mixture.

Further, it is evident from (16) that the above statement applies when the component gases are each taken with the same value of its volume and temperature as in the gas mixture and with the ratio of its concentration to its concentration in the gas mixture equal to unity.

From (10) and (15) it is evident that at very low pressures:

$$\left(\frac{\Sigma p_{ei}}{p} \right)^* = 1 \quad (45)$$

$$\left(\frac{\Sigma C_{ei}}{C} \right)^* = 1 \quad (46)$$

At very low pressures the ratio of the sum of the equilibrium pressures (or equilibrium concentrations) of the gases composing a mixture to the pressure (or concentration) of the gas mixture is unity.

7. THE ENERGY

From Eqs. (1) and (33), we find that at low pressures the energy of a gas mixture can be written:

$$U = \Sigma f_i(T) + \zeta p \quad (47)$$

where the parameter ζ varies with the temperature and composition of the mixture. Hence:

$$U^* = \Sigma f_i(T). \quad (48)$$

At very low pressures the energy of a mixture of real gases is a function of the temperature and composition.

By use of (24) and (26) we can write (1) and (47) to the same degree of approximation in the more convenient forms:

$$U_1 = f_1(T) + \frac{\zeta_1'}{V} \quad (49)$$

$$U = \Sigma f_i(T) + \frac{\zeta'}{V} \quad (50)$$

where ζ_1' and ζ' have somewhat different numerical values from ζ_1 and ζ .

8. THE PRESSURE-VOLUME-TEMPERATURE RELATION

The following treatment is an adaptation of a method which Poincaré¹⁰ used for the case that the relations (3) and (20) hold for all pressures, and which is similar to a method that Phillips¹¹ applied for the case that the isometrics of a gas are strictly linear. We shall use the relations (49) and (24) which apply to real gases at low pressures, and (50) and (26) which apply to mixtures of real gases at low pressures.

Substitution of (49) into the first and second law equation:

$$dS = \frac{dU}{T} + \frac{p}{T}dV \quad (51)$$

gives:

$$dS = \left[\frac{1}{T} \frac{df_1}{dT} + \frac{1}{TV} \frac{d\zeta_1'}{dT} \right] dT + \left[\frac{p}{T} - \frac{\zeta_1'}{TV^2} \right] dV. \quad (52)$$

Since dS is a complete differential:

$$\frac{\partial}{\partial V} \left[\frac{1}{T} \frac{df_1}{dT} + \frac{1}{TV} \frac{d\zeta_1'}{dT} \right] = \frac{\partial}{\partial T} \left[\frac{p}{T} - \frac{\zeta_1'}{TV^2} \right]. \quad (53)$$

The quantities f_1 and ζ_1' do not vary with the volume, hence:

$$\frac{\partial}{\partial T} \left(\frac{p}{T} \right) + \frac{\zeta_1'}{T^2 V^2} = 0 \quad (54)$$

Integration of (54) at constant volume gives:

$$\frac{p}{T} + \frac{1}{V^2} \int \frac{\zeta_1'}{T^2} dT = \Phi \left(\frac{V}{n_1} \right). \quad (55)$$

For all values of the temperature other than zero, Eq. (55) may be written:

$$p = T \Phi \left(\frac{V}{n_1} \right) + \frac{n_1^2 \kappa_1}{V^2}$$

where κ_1 is bounded. From Eq. (24):

$$p = \frac{n_1}{V} F(T) + \frac{n_1^2 \beta_1}{V^2} F(T) \quad (56)$$

whence:

$$\frac{V}{n_1} \Phi \left(\frac{V}{n_1} \right) = \frac{1}{T} F(T) + [\beta_1 F(T) - \kappa_1] \frac{n_1}{VT}. \quad (57)$$

¹⁰ Poincaré, *Thermodynamique*, Gauthier-Villars, Paris, 2nd ed.; p. 160.

¹¹ Phillips, *Jour. of Math. and Physics* **1**, No. 1 (1921).

At very low pressures (57) becomes:

$$\frac{V^*}{n_1} \Phi \left(\frac{V}{n_1} \right)^* = \frac{1}{T} F(T) = \text{constant} = R \quad (58)$$

since a function of the volume can equal a function of the temperature only if each is constant. Hence:

$$F(T) = RT. \quad (59)$$

We would have obtained the same relation by use of Eqs. (50) and (26), and R would have the same value.

Thus Eqs. (23) and (24) for pure gases become:

$$pV = n_1 RT + n_1 \beta_1 p \quad (60)$$

$$pV = n_1 RT \left(1 + \frac{n_1 \beta_1}{V} \right) \quad (61)$$

and (25) and (26) for gas mixtures:

$$pV = \Sigma(n_i)RT + \Sigma(n_i)\beta p \quad (62)$$

$$pV = \Sigma(n_i)RT \left(1 + \frac{\Sigma(n_i)\beta}{V} \right). \quad (63)$$

Hence for real gases at very low pressures:

$$(pV)^* = n_1 RT \quad (64)$$

and for gas mixtures:

$$(pV)^* = \Sigma(n_i)RT. \quad (65)$$

At very low pressures the pressure-volume product for a real gas or for a mixture of real gases is equal to the product of the total number of moles present multiplied by RT where R is a universal constant and T the Kelvin temperature.

9. THE HEAT CONTENT

From the relations (1), (34) and (60) we can write for a pure gas at low pressures:

$$H_1 = f_1(T) + n_1 RT + \eta_1 p \quad (66)$$

where η_1 and its temperature derivative are bounded. Moreover from (47), (34) and (62), there results for a gas mixture at low pressures the relation:

$$H = \Sigma f_i(T) + \Sigma(n_i)RT + \eta p. \quad (67)$$

In (66) and (67), $f_1(T)$ (or $f_i(T)$) is the same function of the temperature as that which occurs in (1). At very low pressures (66) and (67) become:

$$H_1^* = f_1(T) + n_1 RT \quad (68)$$

$$H^* = \Sigma f_i(T) + \Sigma(n_i)RT. \quad (69)$$

10. THE HEAT CAPACITIES AT CONSTANT VOLUME AND AT CONSTANT PRESSURE.

Differentiation of (49) and (50), and of (66) and (67) according to the relations:

$$C_V = \left(\frac{dU}{dT} \right)_{V,n} \quad (70)$$

$$C_p = \left(\frac{dH}{dT} \right)_{p,n} \quad (71)$$

respectively, where the n denotes differentiation at constant composition, gives:

$$C_{V_1} = \frac{df_1(T)}{dT} + \frac{1}{V} \frac{d\zeta_1'}{dT} \quad (72)$$

$$C_V = \Sigma \left(\frac{df_i(T)}{dT} \right) + \frac{1}{V} \frac{d\zeta'}{dT} \quad (73)$$

$$C_{p_1} = \frac{df_1(T)}{dT} + n_1 R + \frac{d\eta_1}{dT} p \quad (74)$$

$$C_p = \Sigma \left(\frac{df_i(T)}{dT} \right) + \Sigma(n_i) R + \frac{d\eta}{dT} p \quad (75)$$

in which C_{V_1} and C_{p_1} refer to pure gases, and C_V and C_p to gas mixtures. Moreover it is evident that at low pressures:

$$C_{p_1} - C_{V_1} = n_1 R + \alpha_1 p \quad (76)$$

$$C_p - C_V = \Sigma(n_i) R + \alpha p \quad (77)$$

where α_1 and α are bounded. At very low pressures the relations (72) to (77) become:

$$C_{V_1}^* = \frac{df_1(T)}{dT}; \quad C_{p_1}^* = \frac{df_1(T)}{dT} + n_1 R \quad (78)$$

$$C_V^* = \Sigma \frac{df_i(T)}{dT}; \quad C_p^* = \Sigma \left(\frac{df_i(T)}{dT} \right) + \Sigma(n_i) R \quad (79)$$

$$C_{p_1}^* - C_{V_1}^* = n_1 R \quad (80)$$

$$C_p^* - C_V^* = \Sigma(n_i) R. \quad (81)$$

At very low pressures the heat capacities at constant volume and at constant pressure of a real gas are functions of the temperature, and those of mixtures of real gases are functions of the temperature and composition.

At very low pressures the difference between the heat capacity at constant pressure and at constant volume for a real gas or for a mixture of real gases is

equal to the product of the total number of moles present multiplied by the universal gas constant R .

From (78) and (79) it is evident that at very low pressures:

$$C_V^* = \Sigma C_{V_i}^* \quad (82)$$

$$C_p^* = \Sigma C_{p_i}^* \quad (83)$$

11. SUMMARY OF THE RELATIONS FOR VERY LOW PRESSURES

It has been shown that the two assumptions for low pressures:

$$U_1 = f_1(T) + \zeta_1 p \quad (1)$$

$$\frac{p_{ei}}{p x_i} = 1 + \xi_i p \quad (2)$$

together with the general laws of thermodynamics are the necessary and sufficient conditions for the following relations to hold at very low pressures:

Relations for real gases

$$(pV)^* = n_1 RT \quad (64)$$

$$U_1^* = f_1(T) \quad (3)$$

$$H_1^* = f_1(T) + n_1 RT \quad (68)$$

$$C_{V_1}^* = \frac{df_1(T)}{dT} \quad (78)$$

$$C_{p_1}^* - C_{V_1}^* = n_1 R \quad (80)$$

Relations for mixtures of real gases

$$(pV)^* = \Sigma (n_i) RT \quad (65)$$

$$U^* = \Sigma f_i(T) \quad (48)$$

$$H^* = \Sigma f_i(T) + \Sigma (n_i) RT \quad (69)$$

$$C_V^* = \Sigma \frac{df_i(T)}{dT} \quad (79)$$

$$C_p^* - C_V^* = \Sigma (n_i) R \quad (81)$$

Equilibrium relationships

$$\left(\frac{p_{ei}}{p x_i} \right)^* = 1 \quad (4)$$

$$\left(\frac{C_{ei}}{C_i} \right)^* = 1 \quad (16)$$

$$\left(\frac{C_{ei}}{C x_i} \right)^* = 1 \quad (17)$$

Additive relationships¹²

$$\left(\frac{\Sigma p_{ei}}{p} \right)^* = 1 \quad (45)$$

$$\left(\frac{\Sigma C_{ei}}{C} \right)^* = 1 \quad (46)$$

$$S^* = \Sigma S_{ei}^* \quad (40)$$

$$U^* = \Sigma U_i^* \quad (41)$$

$$H^* = \Sigma H_i^* \quad (42)$$

$$F_{VT}^* = \Sigma F_{VT_{ei}}^* \quad (43)$$

$$F_{pT}^* = \Sigma F_{pT_{ei}}^* \quad (44)$$

$$C_V^* = \Sigma C_{V_i}^* \quad (82)$$

$$C_p^* = \Sigma C_{p_i}^* \quad (83)$$

¹² When a thermodynamic quantity is bounded as the pressure approaches zero, it is not necessary to include the subscript e since in the region of very low pressures the value of the quantity does not change appreciably with pressure.

It is evident from the derivations given that each of the above relations holds at infinitely low pressures. Hence in each of these relations we may consider that the asterisk denotes "the limit of the quantity (to which the asterisk is attached) as the pressure on the system approaches zero at constant temperature, and subject to certain restrictions on the concentrations of the components." When no chemical reaction between the components of the system is contemplated, the restriction is simply that the composition of the system does not vary; when chemical reaction occurs the restriction is that the system be always maintained in equilibrium, and in this case a variation in composition will occur as the limit is approached. Thus for example, we may write:

$$\lim_{p \rightarrow 0} pV = n_1 RT$$

$$\lim_{p \rightarrow 0} U_1 = f_1(T)$$

$$\lim_{p \rightarrow 0} (C_{p1} - C_{v1}) = n_1 R$$

$$\lim_{p \rightarrow 0} \frac{p_{ei}}{p x_i} = 1$$

$$\lim_{p \rightarrow 0} S = \sum \lim_{p \rightarrow 0} S_{ei}$$

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Breadth of Compton Modified Line

Professors Ross and Clark of Stanford, using the ingenious balanced filter method of Ross, have investigated the shifted line in the Compton effect for antimony, $K\alpha_1$ and $K\alpha_2$, lines scattered from beryllium. In this method the scattering angle is varied so as to vary the shift of the modified line. The scattered radiation is observed with an ionization chamber after passage through a silver filter and then a palladium filter balanced against the silver filter. The difference between the transmissions plotted as a function of the scattering angles exhibits peaks or fluctuations in the curve at the scattering angles of 55° and 75° corresponding to the points at which the shifted lines from $K\alpha_1$, $K\alpha_2$, respectively cross the silver edge of the spectral region defined by the balance filter method.

In view of the fact that the author has published experimental results¹ in which the breadth of the Compton line from molybdenum, $K\alpha_1$, $K\alpha_2$ scattered at nearly 180° from beryllium is too great to permit resolving the α_1 , α_2 peaks, it seems worth while pointing out that these two results are not necessarily discordant. The author's experimental results were accompanied with his theory of the breadth and structure of the Compton line according to which a prominent part of Compton line structure, due to scattering by the free or conduction electrons in metallic scatterers, has a breadth which can best be correlated with the velocities of these electrons required by the Fermi statistics and which furnishes confirmatory evidence of the correctness of the Fermi distribution of velocities for conduction electrons in contradistinction to the older Boltzmann statistics.

According to the author's theory, the breadth of the Compton line, however, depends not only on the velocity distribution

of conduction electrons, but also on the primary wave-length used and on the angle of scattering. In fact, for any given velocity β of randomly moving conduction electrons, the author's theory asserts that the contribution to the Compton line is a small rectangular element having a spectral breadth given by (formula (1), page 647)

$$\Delta\lambda = 4\beta\lambda^*.$$

In this formula, which gives the breadth of the Compton line as a function of scattering angle, the symbol λ^* stands for a wave-length which is defined thus:

$$2\lambda^* = (\lambda_c^2 + \lambda_1^2 - 2\lambda_c\lambda_1 \cos \theta)^{\frac{1}{2}}$$

λ^* is most easily visualized by a diagram. Construct a triangle, one angle of which equals the scattering angle, and having the two adjacent sides to this angle proportional respectively to the primary wave-length λ_1 , and the shifted wave-length λ_c , of the simple Compton theory, for initially stationary electrons. Then the third side of this triangle is proportional to $2\lambda^*$.

On the basis of this formula, the author has computed for the case of Ross' experiment

$$\theta = 75^\circ, \quad \lambda_1 = 469 \text{ X.U.}, \quad \lambda_c = 485 \text{ X.U.}, \quad \lambda^* = 292 \text{ X.U.}$$

$$\theta = 55^\circ, \quad \lambda_1 = 474 \text{ X.U.}, \quad \lambda_c = 485 \text{ X.U.}, \quad \lambda^* = 222 \text{ X.U.}$$

If one assumes in beryllium one conduction electron per atom, this would give a Compton line breadth for Ross' cases of 6.5 and 5X-units, respectively. This refers to the breadth of the line at the base of the part contributed by conduction electrons, which according to the author's calculation seems to come a little below half maximum value. Assuming

¹ J. W. DuMond, Phys. Rev., 33, 643-658 (1929).

two conduction electrons per atom, the corresponding breadths for Ross' cases are 8.4 X.U. and 6.36 X.U. respectively. It seems, therefore, safe to conclude that Ross' resolution of the doublet in the shifted radiation is for the conditions of his experiment not necessarily inconsistent with either the author's theory of Compton shifted line structure or with his published experimental observations.

At the present writing the author, in collaboration with Mr. H. A. Kirkpatrick, has just succeeded in obtaining photographic spectrograms of the Compton shifted line, using Mo $K\alpha_1$, α_2 scattered at 90° from graphite with a maximum inhomogeneity of scattering angle of less than one degree. The unmodified doublet is completely resolved on the negative and the Compton line appears

very broad and diffuse. This work is being done with the fifty-crystal spectrograph described in Review of Scientific Instruments, Vol. 1, No. 2, February 1930.

The author believes that this new instrument at last affords the possibility of investigating the whole question of Compton modified radiation under adequately pure conditions of scattering angle and spectral resolution. We feel that we can now announce with complete assurance that the Compton shifted line is more diffuse than the lines of the primary radiation.

The Raman Effect in Trimethylethylene

In some experiments made a year ago on the Raman effect in trimethylethylene several diffuse modified lines were found. The stronger correspond to infrared wave-lengths $3.44 \pm 0.05\mu$ and $8.4 \pm 0.2\mu$. Several fainter lines were found between these two. An anti-Stokes line corresponding to 8.4μ was also faintly seen excited by the mercury line 4358A. It seems probable that all these lines can be matched by absorption lines belonging to the group CH although no absorption line was found recorded as long as 8.4μ .

Accidental contamination with rubber added a continuous scattering, with a marked denser band beginning near the position of the strongest line, *ca* 4600A. A continuous

spectrum was obtained in about the same position when a little rubber was dissolved in carbon tetrachloride, making it probable that the effect was due to the rubber and not to a change in viscosity of less than one percent. In this case a suggestion of a second very broad band with maximum about 5500A was also found. If these bands were due to Raman scattering it would be necessary to think of the exciting mercury lines as 4046A and 3650A. The light appeared to be partially polarized.

Photoionization of Salt Vapors

The chief interest presented by the photoionization of the vapors of various compounds is that it may afford additional information regarding the structure of molecules. As far as I am aware no such work with the vapors of simple inorganic salts has as yet been done.

In an investigation undertaken by me on these lines with the vapors of halides of various metals, a marked photoionization of these vapors was observed. The illumination was produced by intense ultraviolet light of wave-lengths longer than 1850A. The photoeffect from the electrodes and the walls was negligibly small as compared with the photocurrent from the vapor, in some cases the latter was a hundred times as great as the

photocurrent which could be produced by direct illumination of the electrodes.

On raising the temperature of the salt thermal ionization currents could be observed without illumination, an effect which has been previously extensively studied by G. C. Schmidt and his co-workers (Ann. d. Physik **82**, 664 (1927) **2**, 313 (1929)). The photoionization begins generally at much lower temperatures than the temperatures at which the thermo-current is noticeable.

The salts studied first were TII, TlBr, TlCl. It has been previously shown in this laboratory (Butkow and Terenin, Zeits. f. Physik **49**, 865 (1928), Butkow, *ibid.* **58**, 232 (1929)) that the excitation energy of the first

electronic level of these molecules coincides very closely with the corresponding value for the Tl atom; the figures (in volts) are as follows: 3.4 for TII, 3.6 for TIBr and 3.8 for TICI as against 3.3 for Tl. It seems therefore that the Tl atom has to some extent an individual existence in the molecule and can be excited by light absorption independently of the other component, a view consistent with the fact that these molecules are "atomic" ones.

There arose naturally the question, whether the value of the ionization energy of the molecule would coincide with the ionization potential of Tl. The experiment showed, in fact, the existence of a strong photoionization of these vapors, the active wave-lengths lying on the short wave-length side of certain limits, which are 2140Å for TII and 2070Å for TIBr. Expressed in volts this gives for the assumed ionization potentials of TII and TIBr, 5.8 and 6.0 respectively, whereas the ionization potential of Tl is 6.1 V.

The agreement is sufficiently good to support the view that at these wave-lengths the ionization of the TIX molecules sets in, as the result of the liberation of an electron from the Tl atom. An explanation of the photocurrent by the dissociation of the TIX molecules into ions Tl^+ and X^- , improbable in itself, would give other threshold values than is the case here. It must be noticed that the range of ionizing radiation overlaps to some extent the range of wave-lengths producing the dissociation of the TIX molecules with subsequent emission of certain Tl lines, which has been thoroughly studied before (Terenin, *Zeits. f. Physik* **44**, 713 (1927); Butkow and Terenin, loc. cit.). The wave-length thresholds of these two processes are, however, quite different.

From the known equation: $D_m + I_a = I_m + D_{m+}$, where I_a , I_m are the ionization energies of the Tl atom and the TIX molecule respectively, D_m , D_{m+} —the dissociation energies of the neutral and the ionized molecule,

the value of D_{m+} can be computed to be 2.8V for TII⁺ and 3.3V for TIBr⁺. As the dissociation energies D_m of the neutral molecules are 2.5 and 3.2V respectively, it may be concluded that the molecular ions TIX^+ are more stable than the corresponding neutral molecules; this fact, interesting in itself, is consistent with other known data.

For TICI the threshold was found to be 1860Å, but this value is not quite certain owing to a dubious origin of the salt used in the experiment.

A marked decrease of the photosensitivity in the sequence TII, TIBr, TICI was noticed.

On raising the applied voltage from 50 to 600 V, the appearance of Tl arc lines could be observed in TII, but only during the illumination of the vapor. This can be explained as an excitation of the Tl atoms always present in the vapor, by the photoelectrons liberated from the molecules and accelerated by the field applied. There is, besides, the possibility of various dissociation and excitation processes induced in TII by these electrons.

Other volatile halides, e.g. AgI, PbI₂, PbCl₂, BiI₃, were also investigated, but they gave much smaller photoionization currents, than the Tl halides. In HgI₂ and CdI₂ no measurable effect could be observed.

The possibility of a photoionization seems to be dependent chiefly on the magnitude of the ionization potential of the metallic atom in the molecule, which must fall within the range of the ultraviolet frequencies used. The photoionization is more pronounced in the iodides and decreases in magnitude in the chlorides.

The magnetic mass analysis of the ions produced under various circumstances will facilitate, I hope, to a great extent the interpretation of the underlying processes.

The Raman Effect in Solutions of Sodium Nitrate of Varying Concentration

Experiments suggested by those of Rao on HNO₃ (*Nature*, **124**, 762 (1929)) have been made on the Raman spectrum of NaNO₃ at concentrations of 5, 10, and 30 percent and saturated. Exposures were made varying approximately inversely with the concentration from 39 hours down. The source of light

was a glass mercury arc, and the spectrograph a Hilger D78. The Raman line with frequency difference $1049 \pm 6 \text{ cm}^{-1}$ was found excited by the mercury lines 4358, 4077, and 4046, approximately equally strongly in the different cases, and no new lines were found either in the more dilute or in the saturated solution.

This remained true when the time of exposure for the saturated solution was increased to 15 hours. This line agrees with that found by Carrelli, Pringsheim and Rosen, (*Zeits. f. Physik* 51, 511 (1928)) and is attributed to the NO_3 ion, since they found it in solutions of different salts containing this ion. The present experiment confirms this and shows no indication of NaNO_3 molecules, although from conductivity measurements the partial dissociation theory would have said that nearly two-thirds of the salt was nondissociated in the saturated solution.

The water band was also found excited by the mercury lines 4358, 4077, 4046, and 3650. The water was redistilled. The ordinary

laboratory distilled water spectrum showed many lines, a number appearing like absorption lines although a photograph of the absorption in the region showed nothing. These lines could not be attributed to Raman scattering. The redistilled water spectrum showed only the water band in the region of wave-lengths shorter than 5460A except once a faint suggestion of an absorption line at 4859A, several lines still appeared at wave-lengths greater than 5790A.

The Calculation of Energy Values

A number of modifications of the Ritz method of calculating characteristic numbers have recently been applied to the quantum dynamical problem. I have tried another of these methods, which seems to possess several advantages.

The characteristic functions of an atomic system of N electrons whose coordinates are $(r_1, r_2 \dots)$ are approximated by polynomials of the requisite symmetry,¹ whose separate terms are of the type

$$u(\alpha, r_1) v(\beta, r_2) \dots$$

Taking a hint from the empirical formulae for energy levels, I assume that each of these functions, say v , is a characteristic function of a one-electron system whose nuclear charge

The rule has several advantages: (1) the approximate wave function involves at most N parameters. Others have often used more without obtaining results that are much more accurate than those given by the present choice. (2) It leads to a definite result for the approximate wave function, no matter what the atomic system under consideration may be. (3) Many of the integrals whose numerical values are needed have a simple form. (4) The same functions $u, v \dots$, recur in many different problems, so that when the numerical work required for one has been finished, much of the work for several others is also completed. This will be particularly true in the later parts of the periodic system.

The method has already been applied to

TABLE I

Z	Level	$T/(Z-1)^2$			$\alpha(1s)$	$\beta(2p)$

is, say, β . These various "effective" charges α, β, \dots , are then determined so that the variation integral is a minimum, subject to the condition that the wave function is of the form just described. The justification for this choice of wave function is purely empirical at present, but it is believed that some theoretical justification for it may be found.

the particular case of the normal states of atoms of two electrons,² the result being

¹ This has also been suggested by V. Guillemin and C. Zener, *Zeits. f. Physik* 61, 199 (1930).

² J. Frenkel, *Einführung in die Wellenmechanik*, p. 291 ff. Berlin, J. Springer (1930).

that their term values are $2(Z-5/16)^2$, Z being the true nuclear charge. I have extended the calculations to the $2P$ and $3D$ states with the following results.

In Table I, T is the term value in units of $Rh\text{ cm}^{-1}$; the third column contains the result of a calculation based on the foregoing rule;

which is believed to have been sufficiently accurate. Although there are systematic deviations of the calculated from the observed values of $T/(Z-2)^2$, it is interesting to note that both sequences show a flat maximum near Be II. The calculated values of the screening constants $Z-\beta$ are not strictly

TABLE II. 3^3D-3^1D

	Present method	Perturb. method	Observation

Li II	3.80×10^{-5}	$30. \times 10^{-5}$	2.68×10^{-5}

the fourth, the first-order result of perturbation theory; the fifth, the observed value. The quantities α and β are the effective nuclear charges for the $1s$ and $2p$ electrons, respectively. In the case of the $3D$ states, the screening constant $z-\beta$ proves to be so nearly unity that the Balmer formula may be used to calculate the absolute magnitude of the

comparable with those deduced from the observed doublet separation, but both sequences decrease monotonically.

Theory indicates that the method should be applicable to the 2^3S state of atoms with two electrons, but requires a slight modification for the 2^1S . A rough calculation verifies this. As soon as the calculations for these

Some Peculiarities of the Spectrum of the Tungsten Mercury Arc

In the course of an investigation of sources of ultraviolet radiation, it was found that the new General Electric Sunlamp in a quartz bulb gives a very intense continuous spectrum in the region from 4000Å to 2100Å. The source of the ultraviolet radiation is a 300 watt alternating current mercury arc between

hot tungsten electrodes with the bulb containing about 100 mm pressure of argon. With a Hilger E2 quartz spectrograph, an exposure of 10 to 15 seconds is sufficient to give an intense continuous background. The intensity of the continuous spectrum relative to the line spectrum can be increased by

burning the lamp at a higher voltage or by increasing the pressure of the mercury vapor in the lamp by external heating.

When the temperature of the mercury is increased, the mercury vapor absorption bands appear. The band at 2540A, first described by R. W. Wood (*Astrophys. J.*, vol. 26), is approximately 0.1A wide at a mercury temperature of 220°C (corresponding to a vapor pressure of 32 mm), and spreads toward longer wave-lengths until it reaches about 2576A at 407°C and 2652A at 426°C, (corresponding to a vapor pressure of 2316 mm). Wood found that this band did not extend beyond the resonance line on the short wave side. Our work with this arc, however, shows the resonance line disappearing at approximately 350°C and two narrow absorption bands appearing at approximately 2534A and 2532A. With further increase in the temperature of the mercury these bands merge with the 2540 band until at 426°C there is continuous absorption between 2530A and 2652A, with evidence of further absorption beyond 2652A.

The five fluted bands around 2345A appear between 320°C and 340°C and broaden as the temperature is increased until they extend over a range of about 16A at 420°C. The broadest of the bands is about 3A wide. The increased pressure also affects certain lines

in the region between 3500A and 2100A, some of the lines disappearing entirely at the higher temperatures.

Mercury in a separate quartz absorption cell shows a somewhat different absorption spectrum. The band at 2540A spreads toward the long wave-lengths as the vapor pressure increases until at a temperature of 456°C there is strong absorption of the radiation to 2652A and partial absorption to 2850A, and at 492°C (corresponding to a vapor pressure of 5420 mm) there is strong absorption to 2753A. The band does not extend beyond the resonance line on the short wave side. The fluted bands at 2345A appear at about 340°C and spread to either side until at 460°C the line at 2345A disappears and at 517° (corresponding to a vapor pressure of 7430 mm) the absorption between 2301A and 2350A appears to be continuous.

Further investigation of the absorption bands of both the excited and the unexcited mercury vapor is being made.

Experimental Evidence for the Existence of Quadrupole Radiation

Rubinowicz (*Zeits. f. Physik* 53, 267 (1929)) has shown that spectral lines which violate the transition rule for l or j cannot be explained as dipole radiation, but must be attributed to multipole radiation.

Besides the nebular lines identified by Bowen, the best known line of this type is the green auroral line 5577A. According to McLennan the auroral line is the forbidden combination between the low metastable O I terms 1S_0 and 1D_2 . (The values of these terms have been accurately determined as $^1S_0=76037$ and $^1D_2=93962$ by one of the authors (F.) and will appear shortly in the *Phys. Rev.*)

Assuming that the auroral line is quadrupole radiation, Rubinowicz (*Zeits. f. Physik* 61, 338 (1930)) pointed out that not only those Zeeman components may be observed which correspond to the usual transition $\Delta m = \pm 1, 0$, but also components which correspond to the transitions $\Delta m = \pm 2$. The

latter have zero intensity when viewed longitudinally and were therefore not observed by McLennan and Sommer. According to Rubinowicz all of the above transitions show the same intensity when viewed perpendicularly to the field, with the exception of $\Delta m = 0$, which can only be observed at oblique angles with the field. Measurements of the transversal Zeeman effect thus make possible an experimental test for the existence of quadrupole radiation.

We have photographed the transversal Zeeman effect of the auroral line. The magnetic field was produced by a large solenoid previously constructed and calibrated by one of us (C.) for a precision determination of e/m by the Zeeman effect. With this solenoid it is possible to maintain a field of 7000 gauss continuously. The auroral line was produced by a d.c. discharge of 0.6 amperes through a mixture of argon and oxygen in a tube 30 mm in diameter. The tube

was silvered over the central portion to increase the intensity by multiple reflection. The light leaving the tube transversally through a slit in the silvering was reflected out of the solenoid by a 45° prism. The Zeeman pattern was photographed with a Fabry-Perot interferometer crossed with a prism spectrograph. By placing a thin calcite plate with proper orientation behind the spectrograph slit, each spectral line appeared separated into its π and σ components.

At a field of 2580 gauss and an interferometer separation of 0.6159 cm, the auroral line was resolved into four components. The displacement of the inner components was $0.92\Delta\nu_{\text{norm}}$, that of the outer components was $1.96\Delta\nu_{\text{norm}}$. The theoretical factors are

1 and 2, respectively. As was predicted the undisplaced line did not appear. We found that the outer components were polarized perpendicular to the field, and that the components displaced by $\Delta\nu_{\text{norm}}$, which in the normal effect are polarized perpendicular to the field, are in this case polarized parallel. This is in complete agreement with the theory of Rubinowicz.

We intend to investigate the Zeeman effect of other forbidden lines.

Mobility of Na^+ Ions in H_2

The results of studies of mobilities of ions in mixtures showing the great importance of traces of impurities on mobilities,¹ the studies of Erikson² on the change of mobilities of positive ions with age at atmospheric pressures including the effects of impurities, and the prominence recently given the change of charge of initially ionized atoms and molecules in gases reported by Kallman and Rosen,³ indicating as previously emphasized the total ignorance as to the nature of the ionized carrier,^{4,1} led to the present investigations the first results of which it is desired to report at this time.

It seemed essential by as nearly an absolute a method as possible to measure the mobilities of a type of initially ionized carrier which would only reluctantly alter its charge in gases of reasonable purity over very short time intervals. To this end it was attempted to measure the mobilities of positive Na^+ ions from a Kunsman⁵ source, using a high frequency square wave form oscillator in fairly pure gases at low pressures. From the nature of the Kunsman sources the gas chosen was hydrogen purified by a process previously used by the writer.* A Kunsman source of positive ions with a square wave form oscillator, using the original Rutherford A.C. method with positive ions instead of negative ions, should: (1) give absolute values of the mobilities with no disturbing effects of gauzes as encountered in other A.C. methods,⁶ and with ions definitely emerging from one plane of the parallel plate electrode system; (2) give ions which retain

their positive charge in H_2 because of their low ionization potential; and (3) be capable of extension to very short time intervals. The chamber used was a brass one of a type previously described⁷ with electrodes altered to suit the Kunsman source. The source was a coating of Na catalyst, kindly sent the writer by Dr. Kunsman, on a thin Pt foil, spot welded onto a small oven of Ni containing a Pt spiral heating element insulated from it by "Insolute" cement. In practice it was heated to about 700°C and gave a copious supply of $+$ ions. It was mounted in the center of the upper plate of a parallel plate condenser in the gas, the lower plate going to ground through an electrometer system. The plate distance was 1.2 cm. By means of an oscillator first designed by J. L. Bowman,⁸ built here by Mr. J. E. McVay and adapted by the writer, good square wave form alternating potentials of from 10 to 150 volts with frequencies varying from 500 to 25,000 cycles per second have been achieved. It is probable that the upper frequency limit can be considerably extended. The first results covered a range of pressures from 0.5 to 7 cm of Hg and appeared of sufficient importance to report at this time, as the work will be interrupted for the period of a month or two by external demands on the writer.

Mobilities in H_2 were observed, beginning

* The H_2 was passed over hot Cu, NaOH, CaCl_2 , two meter long tubes of P_2O_5 and a special double liquid air trap immersed in liquid air.

at between 8 and 10 cm/sec. per volt/cm for $+$ ions at the lower frequencies, (500 cycles to 2000). Above frequencies of 2000 cycles the values of the mobilities increased, reaching a maximum of about 21 cm/sec. per volt/cm above 5000 cycles and remaining there up to 25,000 cycles. Between the lower and higher frequency values the curves indicated by their slopes the probable existence of two carriers present in varying proportions, which made the accurate assignment of mobilities uncertain. This uncertainty will have to remain until the new and somewhat difficult techniques involved shall have been perfected. Hence the results can be considered only as preliminary. The reduced mobility depends primarily on frequency and does not appear to depend on pressure. The correction of the results for temperature was not attempted, first, because the temperature correction for mobility is very uncertain⁹ and, secondly, it was not desired to encumber this already complex apparatus at this stage with the necessary added refinements. Since this work was done at constant density the temperature effects will not be great.

The results indicate that Na^+ ions in H_2 within 2×10^{-5} seconds (reciprocal of twice the frequency) after liberation have a little more than double the value of the mobility of the normal ions. These are probably the Na^+ atoms moving in the gas and impeded by their electrostatic attractions only. In 10^{-3} seconds these ions have in part either exchanged charges with other molecules or attached to molecules of H_2 , H_2O vapor (present in traces), or some other molecules to form molecular ions. Their mobility is of the order to be expected of the normal positive ions in H_2 as measured by an absolute method.⁶ The process (judging from the nature of the

curves) appears to be a process similar to that observed by Erikson² in his ageing experiments, that is a process which takes place in a single step. The present results differ from Erikson's in the much greater change in mobility occurring, an action which could be ascribed to the use of initial relatively stable Na^+ ions.

Note: Temperature measurements made since this letter indicate average temperatures of less than 130°C in the gas space between the plates. This lowers the average density by a factor of about 0.7 between the plates and indicates that all mobility values reported may be too high in absolute magnitude by a factor less than 1.43. It does not alter the relative changes with frequency.

The Interaction Between Excited and Unexcited Hydrogen Atoms at Large Distances

Eisenschitz and London¹ have recently pointed out that when two similar atoms in different quantum states interact with one another a first order calculation of their mutual energy yields an inverse R^3 term corresponding to a dipole interaction. This term is the controlling one for large values of the internuclear distance R and may yield an energetic order for the different molecular terms at large distances quite different from that which occurs at short distances. As an example they cite the two quantum II

states of the hydrogen molecule whose potential energy curves were computed in first order approximation by Kemble and Zener.² For small internuclear distances the energetic order of the states is $H_{12}^{12} > H_{10}^{10} > H_0^0 > H_{11}^{11}$ as shown by Kemble and Zener, while for large distances the predominance of the $1/R^3$ term leads to the energetic order

¹ Eisenschitz and London, Zeits. f. Physik **60**, 491 (1930).

² Kemble and Zener, Phys. Rev. **33**, 512, (1929).

$H_{12}^{12} \leq H_9^9 > H_{10}^{10} \leq H_{11}^{11}$. The state $U_9(^1\Pi_+)$ in the notation of Eisenschitz and London) whose potential energy curve shows a marked minimum in the region of small values of R has a positive energy of interaction for large values of R corresponding to a repulsive force between the atoms. Similarly the state $U_{10}(^1\Pi_-)$ which shows marked repulsion at short distances, yields a weak attraction at very large distances.

the exact first order computations of Kemble and Zener to the internuclear distances $R=5, 6, 7, 10$. The results are shown in the accompanying table and figure.

The curves show that the crossing-point of the "potential" energy curves for the states 9 and 10 occurs farther out than supposed by Eisenschitz and London. Also the maximum in the potential energy of the state 9 and the minimum for the state 10 are less

TABLE I

R	H_9^9	H_{10}^{10}	H_{11}^{11}	H_{12}^{12}
	(volts above E_0)			
5	-0.21	0.27	-0.44	0.43
6	-0.038	0.057	-0.181	0.162
7	0.016	0.008	-0.081	0.068
10	0.014	-0.014	-0.016	0.016

As the computations of Kemble and Zener were not extended to internuclear distances larger than $R=4$ (here the unit of distance is the radius of the innermost Bohr orbit for the H atom) Eisenschitz and London made a necessarily crude interpolation between the asymptotic $1/R^3$ formula and the curves

pronounced than their interpolation would indicate, being almost imperceptible when plotted on the scale of the original graph of Kemble and Zener.

In the course of the computation here reported we have found the following misprints in the paper of Kemble and Zener.

Errata to paper by Kemble and Zener, Phys. Rev. 33, 512 (1929).

p. 525, Eq. (28): the second term in square brackets should be multiplied by $1/4$ to read

$$\frac{1}{4} \left(1 + R + \frac{R^2}{3} \right) \left(1 + \frac{R}{2} + \frac{R^2}{12} \right)$$

p. 526, Eq. (29): the sign of the third term in the right hand member should be positive.

p. 530, Eq. (35): should read

$$K_2^{(2)} = \frac{R^4}{3840} \int_1^\infty (\lambda^2 - 1)(\lambda^2 + 1/7) \left\{ (3\lambda + R)e^{-3\lambda R/2} - \left(\frac{3\lambda^2 - 1}{2} \right) e^{-\lambda R/2} [S'Ei\{- (\lambda + 1)R\} - SEi\{ -(\lambda - 1)R\} - S \ln \left(\frac{\lambda + 1}{\lambda - 1} \right)] - 3S\lambda e^{-\lambda R/2} \right\} d\lambda.$$

given by Kemble and Zener for short distances. This interpolation enabled them to estimate the positions and values of the minimum point in the H_{10}^{10} curve and the maximum in the H_9^9 curve. At London's suggestion, however, the writers have now extended

BOOK REVIEWS

Physique Moderne. GAETANO CASTELFRANCHI, (Translation from the Italian by M. A. Quemper de Lanascot), 2+660 pp., 147 figures, Albert Blanchard, Paris, 1930, Price 70 francs.

This is a summary of modern physics, written for the educated layman and for the scientist whose work lies outside the field of physics, rather than for the physicist or for the student of physics. For the most part, the mathematics is subordinated to such a degree that a person who has, or who once had, a slight acquaintance with the calculus, will be able to follow the treatment. The book differs somewhat in subject matter from volumes in English which have a similar purpose. An introductory chapter deals with history and with the most elementary facts in regard to atoms and molecules. There is a chapter on the classical theory of light and one which reviews the kinetic theory of gases from an elementary standpoint. Chapters IV and V on the Brownian movement and fluctuation phenomena are entertaining and give considerable insight into the physics underlying the statistical equations which govern these subjects. There are conventional chapters on special relativity and on electrons and positive rays. Then we have a discussion of x-rays, the determination of atomic numbers with their aid, and the structure of crystals. A chapter on radioactivity introduces the nuclear atom, which is first discussed from the standpoint of Rutherford's early scattering experiments. The concept of quanta is introduced via the black-body-radiation route. Bohr's theory of hydrogen is treated much as it is in any elementary English book on atomic structure. Chapter XIV develops the elements of generalized dynamics and applies them to the Zeeman and Stark effects. In the same chapter, we find a very brief account of line and band spectra and of Pauli's principle. Then we encounter specific heats, photoelectric effects (including a brief section on the experiments of Auger), the Compton effect, and other experiments on the structure of radiation. The treatment of magnetism is quite pleasing.

As the author says, his discussion of wave mechanics follows closely that of Darrow, published in the "Bell System Technical Journal" for 1927. The author's decision to do this is commendable, for the reviewer knows of no clearer treatment than that in Darrow's article. The principal application of wave mechanics given in this chapter is that of electron diffraction. The discussion of experiments on this subject is well written. The book ends with a chapter on the new statistics.

No doubt this book will be well received by persons who speak the Romance languages. Its subject matter is already well covered in English by a variety of entertaining and well written books, such as those of Darrow, Andrade, and Haas. The treatment is superficial and the book is not to be recommended as mental food for the serious student of physics. However, this criticism must not be interpreted severely, for the reviewer believes that the volume is well suited to the class of readers for whom it was obviously intended.

ARTHUR E. RUARK

Essai sur les Principes de la Thermodynamique. I.-N. LONGINESCU, with a preface by A. Boutaric, 80 pp., 13×20 cm. Société d'Éditions Scientifiques, Paris, 1929.

In this essay an attempt is made to embrace under the same broad point of view the First and Second Laws of Thermodynamics and the Principle of Least Action. This is done by a quasi-logical deduction from certain general philosophical considerations, among which the notion of causality is important. I do not suppose, however, that even the author would claim that this deduction has any binding logical force, or that more has been achieved than to show in a suggestive way that the notions of thermodynamics fit consistently into a broader sort of physical outlook. The work as a whole may be described as a pleasantly sophisticated essay, which the physicist already familiar with thermodynamics may read with a certain satisfaction, but which is not intended for the beginner or for the physicist who is seriously interested in resolving the logical difficulties in thermodynamics emphasized by recent developments.

P. W. BRIDGMAN

Radio Technic. VI. Die elektrischen Wellen. F. KIEBITZ. Pp. 125, 28 figs. Walter de Gruyter and Co., Berlin. Price RM 1.50.

This is a thin book of pocket size, the sixth of a series dealing with radio practice each by a different author and appearing under the general classification of "Sammlung Götschen." The booklet under review is concerned with an elementary exposition of the nature, propagation and reflection of electromagnetic waves and their radiation and reception by practical antennas and antenna systems.

The treatment is brief and in general takes the form of stating the equations of interest and considering their numerical application to commonly encountered oscillation circuits and radio antennas. The author usually gives the range through which a quantity under consideration may be expected to vary in practice. Although elementary, the treatment is sound and accurate, qualities not found in a great deal of the literature on radio recently appearing.

H. E. HARTIG

Die Grundgedanken der neueren Quantentheorie. O. HALPERN AND H. THIRRING. Pp. 241. J. Springer, Berlin, 1929.

This article is a separate issue from volume 8 of the annual "Ergebnisse der Exakten Naturwissenschaften." There are four chapters: Relativity and electron spin, One body problems, Many body problems, and Interpretation of the theory. The first chapter includes an account of the Dirac electron theory. The second treats a wide variety of problems, oscillator, rotator, hydrogen atom, radioactivity, dispersion and Compton effect, in a concise and simple manner. The third discusses symmetry of the eigenfunctions and simple applications to the helium atom, to band spectra, and gives an account of the new statistics. The last chapter gives an unusually clear account of the statistical interpretation and the uncertainty relation.

E. U. CONDON.

The Conduction of Electricity through Gases. K. G. EMELÉUS. Pp. X+94, 37 figures. E. P. Dutton and Co. Inc., New York City. Price \$1.10.

This book is one of a series of small monographs on physical subjects, edited by B. L. Worsnop. The author confines himself to a treatment of electrical discharges at low gas pressures. He condenses into a few small pages a great deal of information regarding the complex phenomena involved, and points out and briefly discusses some of the outstanding problems of the subject. A chapter is devoted to exploring electrodes.

JOHN ZELENY

THE PHYSICAL REVIEW

THE INCOMPLETE PASCHEN-BACK EFFECT

By J. B. GREEN

MENDENHALL LABORATORY OF PHYSICS, OHIO STATE UNIVERSITY

(Received May 23, 1930)

ABSTRACT

Darwin's calculations for the Zeeman effect have been applied to the most noted examples of discrepancy between the older quantum theory and experiment, those of the Cu $^2P^2D$ multiplet, and the Mg and Be $^3P^2S$ multiplets. The positions and intensities of the lines calculated are in very good agreement with the experiment. The distorted Zeeman patterns of $^3P^2D$ of Mg and $^2P^2D$ of Na are attributed to the action of the magnetic field on 3P and 2P separations.

HEISENBERG and Jordan,¹ and Darwin² have applied the new quantum mechanics to the calculation of the standard Zeeman effect at all field-strengths. This had previously been done only for weak and strong fields, but not for intermediate field-strengths. Kronig³ and Fowler⁴ have also given rules for intensities. Mensing⁵ has applied these results to the case of the $^2P^2D$ multiplet of sodium, and to the $^3P^2D$ multiplet of Mg, and has shown that the observed intensities are in excellent agreement with the theory.

In both of these cases, however, the D separation is practically zero, and we therefore have the case of a very strong field for the D separation while it is a very weak field for the P separation. In this paper the author has sought for some intermediate cases in which the field-strength gives separations of the same order of magnitude as the Zeeman separation.

I. THE SPECTRUM OF COPPER

The most conspicuous example of this sort is given by the excellent work of Back⁶ on the $^2P^2D$ multiplet of copper, $\lambda\lambda 5220, 5218, 5153$. In this case, the 2D separation is 6.90 cm^{-1} while the Zeeman separation is 1.76 cm^{-1} . From Darwin's work we get the formula for the positions of the levels in the magnetic field, W

¹ Heisenberg and Jordan, *Zeits. f. Physik* 37, 263 (1926).

² Darwin, *Proc. Roy. Soc. A*115, 1 (1927); see also K. Darwin, *Proc. Roy. Soc. A*118, 264 (1928).

³ Kronig, *Zeits. f. Physik* 31, 885 (1925).

⁴ Fowler, *Phil. Mag.* 1, 1079 (1925).

⁵ Mensing, *Zeits. f. Physik* 39, 24 (1926).

⁶ Back, *Ann. d. Physik* 70, 333 (1923).

$$\begin{aligned}
& - a_{m_l-1, m_s+1} \beta (l - m_l + 1) (s + m_s + 1) \\
& \quad + a_{m_l, m_s} [W - \beta \cdot 2m_s m_l - \omega(m_l + 2m_s)] \\
& \quad - a_{m_l+1, m_s-1} \beta (l + m_l + 1) (s - m_s + 1) = 0.
\end{aligned}$$

The a 's are numerical coefficients related to the intensities. We write down this equation for every permitted value of m_s and m_l and group the equations thus found into sets in which $m_s + m_l = m$, is the same. The determinant of each group thus found gives us the values of W for that particular value of m . For the intensity formulae, the reader is referred to Darwin's work.

In the case of the Cu multiplet, the value of $\beta = 6.90/5 = 1.38 \text{ cm}^{-1}$ for the 2D levels, and $248.3/3 = 82.77 \text{ cm}^{-1}$ for the P levels, while $\omega = 1.76 \text{ cm}^{-1}$. The results are given in Table I.

(The multiplet $^2P^2D$ of Cu, $H = 37,000 \text{ g}$)

* See text.

A study of the table shows that the newer theory gives much better agreement with experiment than the older theory for 5218 and 5220 except in one component 5220.433. All the other exceptions are very faint lines, which are too difficult to measure with any degree of accuracy. The distortion of intensities is also in the direction indicated by the newer theory.

5153 according to the new theory should be shifted 0.029Å to the red. This amount has been subtracted from all the calculated wave-lengths to show the distortion of the pattern, in almost complete agreement with the experiment.

II. THE SPECTRUM OF BERYLLIUM

Beryllium furnishes a very good example for the theory, since the 3P separation is very small, much smaller, in fact, in comparison with the field-strengths available, than the 2D separations of copper. We are, however, faced with a difficulty, in that the theory has been worked out for the "standard" Zeeman effect. This means that the coupling between the l and s vectors must be such that the ordinary Landé g and γ rules are obeyed. In the case of Be, we should expect the ratio $\Delta\nu_{21}/\Delta\nu_{10}=2:1$ whereas Back⁶ has found 3.58:1. The total separation is 3.02 cm^{-1} and if we take β for the P_{21} separa-

Fig. 1. The Zeeman effect of the Be $^3P^3S$ triplet. Lengths of lines indicate intensities. Dotted lines indicate parallel polarization, full lines perpendicular polarization, dot-and-dash lines double polarization. a indicates components of 3322.423. b indicates components of 3322.162. c indicates components of 3322.090.

tion, we get 0.59 cm^{-1} while for the P_{10} separation it is 0.33 cm^{-1} . Goudsmit⁷ has shown, however, that the γ -sum is independent of the l - s coupling and hence β has been chosen as $3.02/6 = 0.503 \text{ cm}^{-1}$.

The results are shown graphically in Fig. 1 for the $^3P^3S$ triplet at $\lambda 3322$. While they are not so satisfying as the results for Cu, they are still seen to be very good indeed. Two discrepancies in polarization are apparent, and the author has no explanation for these. The presence of a σ -component of 3322.455 is not accounted for by the theory. Back⁶ has attempted to account for the double polarization of the component of 3322.358 by saying that a σ -component of the line b has "crossed" a π component of the line a . The new theory shows no need for such an explanation, the double polarization being predicted.

III. THE SPECTRUM OF MAGNESIUM

The $^3P^3S$ triplet of magnesium, $\lambda\lambda 5183, 5172, 5167$ has been chosen as an example. Here, the 3P separation yields $\beta = 10.09 \text{ cm}^{-1}$, and from Back's

⁷ The Structure of Line Spectra, McGraw-Hill Company, 1930.

observations $\omega = 1.88 \text{ cm}^{-1}$. The results are indicated in Table II. The intensities are relative only within one line and not from line to line. The calculated shifts of the lines are in general in the correct direction, while the intensities are in excellent agreement with experiment.

TABLE II.

	66.342	66.293	66.366	1	1.5	2

Back⁸ has also measured the Zeeman effects of the $^3P^3D$ multiplet in magnesium, in which the 3D separation has disappeared. Here, too, the patterns are distorted, and not so simple as one is at first led to believe. The photographs in Back-Landé, "Zeemaneffekt und Multiplettstruktur" show this effect very clearly, and it is to be attributed to the fact that the magnetic field is beginning to affect the 3P separations as it does in the above example. In the $^2P^2D$ multiplet of sodium a similar effect is also taking place, and the pictures show a markedly distorted Zeeman pattern.

FINE STRUCTURE OF THE *K*-RADIATION OF THE LIGHTER ELEMENTS

BY LAWRENCE Y. FAUST

RANDAL MORGAN LABORATORY OF PHYSICS, UNIVERSITY OF PENNSYLVANIA

(Received May 19, 1930)

ABSTRACT

A vacuum spectrograph of simple construction is described in which it is possible to maintain bombarding currents of 150 milliamperes. With a line grating on glass (1179 lines per mm) photographs, some measurable in the second and third orders have been obtained of the soft x-radiation from beryllium, boron, oxygen and carbon, also from tungsten and certain heavier elements. Under analysis with a thermoelectric densitometer the *K* lines of the lighter elements, excepting oxygen, were found to be complex. The *K*-radiation of boron compounds contained 13 components, that of "pure" boron four, that of carbon nine whereas the beryllium radiation was still more complex. The relative intensities of these components was shown to depend on the energy used in stimulating them. The representative wave-length selected for the *K α* line was for oxygen 23.7A, for boron 69.3A, for carbon 45.3 while for beryllium the radiation embraced more than 15A with maxima at 107.2, 113.2 and 118.7A. The complex structure is thought to be partly a true fine structure and partly a system of satellites due to interaction with associated dissimilar atoms. A possible hypothesis is suggested in explanation of these results.

INTRODUCTION

THE possibility of diffracting soft x-rays from line gratings at small glancing angles was first pointed out by Professor A. H. Compton,¹ in 1923. Since that time important advances have been made, especially by Thibaud,² in the technique of this method, resulting in a number of valuable contributions to our knowledge of the frequencies and inter-relations of spectral lines in the soft x-ray region. Thibaud³ has measured the *K* lines of carbon, oxygen, nitrogen and boron and the *L*, *M*, and *N* radiations of several elements of high atomic number. Other investigators including Hunt,⁴ Osgood,⁵ Weatherby⁶ and Howe⁷ have concentrated on the measurement of the *K* line of carbon in view of its possible value as a calibrating or reference line. Söderman⁸ has made careful measurements of the *K* lines of the elements between magnesium and beryllium with the exception of neon. In addition to these wave-length measurements Bazzoni^{9,10} Faust and

Weatherby have studied the fine structure of the *K* lines of carbon and boron by densitometric methods.

It is evident that the line grating offers amongst other advantages the best means for investigating the *K*-radiation and associated *K*-absorption edges of the light elements. There is some reason to suspect that with the light elements the proximity of the *K* level to the exterior of the atom may cause a deviation from the simplicity of structure characteristic of *K* lines of the heavier elements. However, the researches listed above were for the most part carried out with too low resolving powers to bring out any fine structure in the *K* lines if such structure existed. The single exception to this statement is in the work of Bazzoni, Faust and Weatherby who densitometered the lines obtained in the first, second and third orders from a grating of 1179 lines per mm. These workers reported that the *K* line of carbon contains four components lying between 44.2, 44.9, 45.4 and 46.2A and that the *K* line of boron is of still more complex construction.

The investigation reported on in the present paper was undertaken to check in greater detail the measurements reported by these last mentioned authors and to extend such measurements to other elements of low atomic number.

THE APPARATUS

The apparatus consisted of a special vacuum spectrograph constructed of brass pipe in a design similar to that of Weatherby.¹¹ This apparatus differed from Weatherby's in several particulars. In the first place it was of larger diameter permitting the use of a photographic plate 5" long at a distance of 40 cm from the grating. In the second place the anode-cathode structure was altered to make closer adjustment of clearances possible and to obtain a higher electron current. Both anticathode and filament were mounted on standards attached to a single plate which was wax-sealed to the spectrograph. A spiral filament was centered in an adjustable steel focusing ring coaxial with the anticathode. This ring, which formed one of the filament leads, was earthed and was separately water-cooled by a jacket surrounding the anticathode and insulated therefrom by a Pyrex tube. The other filament lead and the anticathode itself were also each water-cooled and were suitably isolated electrically by Pyrex insulation. The maximum clearance between the cathode and anticathode structure did not exceed 1/8 inch. This design incorporates the advantages of Dershem's¹² tube but is much simpler.

In order to prevent the fogging of the photographic plate as much as possible, carbon paper was introduced into the path of the direct and reflected beams. Considerable scattering resulted from the use of carbon paper, and later aluminum foil was substituted. This substitution resulted in producing clearcut, sharply measurable images of the direct and reflected beams.

¹¹ Weatherby, reference 6.

¹² Dershem, Journ. Optical Society of America 18, 127 (1929).

Eastman x-ray plates were used in all the work with exposures varying from 15 minutes to six hours, three hours being the average.

The current to the anticathode was usually approximately 60 m.a. The driving potential was obtained from d.c. generators in series. A vacuum as low as 10^{-4} mm could be obtained in the spectrograph during operation by the action of a set of diffusion pumps.

The width of the two slits used in collimating the x-ray beam was 0.1 mm or less. The width of the grating used was 2 mm.

At this point attention may be called to the fact that Thibaud² has investigated the collimating properties of a grating at grazing angles. He obtains a formula for the variation of diffraction angle with the grazing angle.

$$\frac{di}{d\theta} = \frac{\theta/2}{(2n\lambda/d + (\theta/2)^2)^{1/2}}.$$

Thus when $\theta = 0$ the diffracted beam is parallel. The maximum variation of θ in this work due to the width of the grating and the width of the slits was $\Delta\theta = 5'$. Whence for a grating of 1179 lines per mm with an angle 3° at 50A, $di/d\theta = 0.2$. Thus corresponding to $5'$ for $\Delta\theta$ we have $1'$ change in i which corresponds at 50A to about 0.08A or about the experimental limit of accuracy. In general the values of θ and $\Delta\theta$ were about half the above values whence the error would be roughly 0.02A which is well within experimental error. It is therefore apparent that in the apparatus as used in this work errors due to lack of perfect collimation of the beams were negligible.

MEASUREMENTS

The determination of the wave-length of a line is dependent (Fig. 1) on the measurement of the angles α and θ and the grating constant d used in the formula:

$$n\lambda = 2d \sin(\alpha/2) \sin(\alpha + \theta)/2.$$

The constant d , obtained by the usual procedure employing the 5461 line of the Hg arc was found to be 8481.8A corresponding to a ruling of 1179 lines per mm. The grating used was furnished by Professor R. W. Wood, to whom we hereby acknowledge indebtedness. $\tan \theta$ can be obtained by

Fig. 1. Diagram of apparatus.

dividing the distance between the direct beam (BC , Fig. 1.) of x-rays passing by the grating and the beam (DE) reflected from the surface of the grating by the perpendicular distance (GA) from the effective center of the grating to the photographic plate.

The measurement of the distance GA was made on a comparator by comparison with a standard meter. The accuracy of this measurement was within 0.05 mm in 40 cm. Since care was taken to insure that the entire face of the grating was in the path of the incident beam, this measurement should correspond to the equivalent distance between grating and plate.

The distance BC to DE was found from a direct measurement on a Hilger traveling micrometer microscope of the extreme edges of the direct and reflected beams corresponding to the distance BE . This distance divided by the distance, GA , of the plate from the grating was taken as the corrected value for $\tan \theta$. An examination of Fig. 1 shows the justification of this procedure. BC is the direct beam image as found on the plate. In the absence of the grating this beam would extend from C to A . Thus AB is the position of the direct beam cut off by the grating and is therefore the effective direct beam. Then $BD + AB/2 + DE/2$ represents the real distance between the reflected beam and effective direct beam. The distance AB is measured by DE since the width of DE is due to the divergence of the direct beam. Whence $BD + AB/2 + DE/2 = BE$.

Having determined θ we find α by measuring $\alpha + \theta$. $\tan(\alpha + \theta)$ is equal to $BF + AB/2$ divided by the plate distance GA . In order to get $BF + AB/2$ it is necessary to add to BE which has been found already, the distance $EF + DE/2$.

Since the measurement of fine structure requires wave-length determinations for each component in the image F , the measurement of $EF + DE/2$ was carried out directly on the vacuum thermocouple densitometer. The width of the entrance slit in the diaphragm over the plate under investigation was 0.05 mm and this was therefore made the distance between successive plate settings in the line density measurements of the plates. To the moving part of the densitometer was attached a bar with fiducial mark which could be followed with the micrometer microscope and thus used to measure the distance that the plate moved.

In making a measurement the reflected line was placed in front of the densitometer slit. The plate was moved until the peak of the reflected line was found and the corresponding position of the fiducial mark was read on the micrometer. The plate was moved on its carriage until the diffracted line to be measured was near the slit. Readings on the galvanometer were taken every 0.05 mm from this point across the width of the diffracted line. Whenever the readings indicated a peak in the line, the position of the fiducial mark was read with the micrometer. The wave-length of each of these peaks was determined thus independently of the others in every case.

Curves produced by plotting the galvanometer deflections against wave-length proved to be reproducible in independent runs, thus suggesting the absence of any serious errors in this part of the work.

With the procedure described, measurements have been completed for the K lines of carbon, boron, oxygen and beryllium. These have been obtained in some cases in three orders. The combined effect of intensity of the line image and variation in dispersion for the different orders determined in

each case which order would give the best resolution of the fine structure under densitometer analysis.

CARBON

The lines of carbon were present on every plate although no carbon was placed on the anticathode. The source of this carbon is probably the grease vapor present at all times in the apparatus. In the 40 plates taken in this particular phase of the study (serial numbers 79 to 119) about 20 carbon lines were studied under the densitometer, the others being either too weak or too strong to give good resolution of the fine structure. Under visual observation most of the carbon lines appeared as continuous broad bands with maximum intensity on the short wave side. However, in several instances where small grazing angles were used, the first order carbon line appeared as a doublet, the shorter wave component being considerably the stronger.

A plot of the densitometer results obtained from a typical carbon line is shown in Fig. 2. Here the peaks indicate diminished transmission through the plates, i.e., the intensity maxima of x-radiation. It is apparent that here

Fig. 2. Plot of densitometer results obtained from a typical carbon line.

we have a complex curve made up of several components. An attempt has been made to analyze this net curve into its constituents, a possible combination being shown in Fig. 2. An examination of this curve shows a rapid rise in intensity from the short-wave side to the first peak at 44.70 Å. A number of peaks follows with a gradual decrease in intensity to 46.20 where the curve again breaks in a sharp descent followed by a number of less prominent maxima. The small change of slope in the curve at 44.2 Å is a real effect and can be observed on all the curves of the carbon line. This demonstrates that the densitometer yields results sufficiently reproducible to attach a meaning even to a change of slope in the curve. The resolved lines shown in the figure are of course arbitrary to some degree. The position and magnitude of these components as shown do not represent the only way in which this curve could be built up. But little weight can be placed on the relative intensities of the minor components since that depends to a large degree on the method of choosing them.

The intensity of the line was found to depend on applied voltage. Although in general in soft x-ray spectroscopy the line intensity increases with

¹³ Dershem, Phys. Rev. 34, 1015 (1929).

the voltage and with increasing plate current, we find in the case of carbon that there is a decrease in line intensity with increase of these factors. This is in accord with the observations of Dershem¹³ who explained the effect as due to the burning off of the carbon from the anticathode by the greater energy used. Thus only faint carbon lines appeared at 2700 volts.

Fig. 3. Densitometer curve of the first order carbon line on a plate taken at 2300 volts.

Fig. 4. Densitometer curve of the first order carbon line on a plate taken at 1500 volts.

It was found that the relative intensities of the components of the lines are dependent on the driving potential, the shorter wave components increasing in intensity relative to the long wave components at higher voltages. This interesting relation was specifically investigated by taking two series of plates under similar conditions excepting that the driving voltage for the one series was 1500 to 1600 volts and for the other series 2300 to 2800 volts.

Fig. 5. Densitometer curve of a third order carbon line on a plate taken at 2500 volts.

Curves in Figs. 3 and 4 illustrate the different intensity distributions obtained in these tests. Fig. 3 is the densitometer curve of the first order carbon line on a plate taken at 2300 volts. This line under visual observation appeared as a doublet. A clearly defined peak is seen here at 43.3 Å. The curve then rises to a sharp maximum at 44.1 Å and shows two more distinct

peaks at 45.40Å. Comparison with Fig. 2 shows that the small change of slope in that curve has now risen to the chief peak, the longer wave peaks being of less intensity. This is the case for all curves of lines taken at voltages of 2300 volts or more and therefore shows a shift of the maximum to the short wave side with increasing voltage.

Fig. 4 is a first order carbon line taken at 1500 volts. The principal peak is now at 45.3Å with a second peak at 46.25. The short wave maxima have become reduced in intensity to mere kinks in the curve.

Fig. 5 is a densitometer curve of a third order carbon line showing unusually good resolution of the four principal maxima of the curve. This plate was taken at 2500 volts.

TABLE I

Plate No.	Order	Voltage	Wave-lengths of components of carbon.

Ave. values			42.66	43.23	44.05	44.66	45.33	46.20	46.60	47.21
										47.70

Taking all of the curves together there appears to be sufficient reason for concluding that the carbon K line contains 9 components centered about 42.7, 43.2, 44.0, 44.7, 45.3, 46.2, 46.6, 47.2, and 47.7Å. We may also conclude that the relative prominence of these components and therefore the apparent position in the frequency scale of the unresolved line depends on the driving voltage, the maximum being 45.3Å at 1500 volts and at near 44.0Å at 2500 volts.

There is some uncertainty in the assignment of the title " $K\alpha$ " to any particular component because of this shift in the maximum from 44.0 to 45.3Å. Whatever the reason for the shift may be, it seems probable that the rate of decrease in intensity with decreasing voltage will be greater for the minor components than for the principal K line. Now since the 45.3Å component was the maximum at 1500 volts, the lowest voltage at which lines could be obtained, it is perhaps justifiable to assign to the $K\alpha$ line of carbon the wave-length 45.33Å.

No explanation can be offered at this time as to the significance of the fine structure here shown. Dr. C. B. Bazzoni has suggested that there is a possibility that the energy due to the excitation potentials of the other elements in combination with carbon interacts with the K -radiation of carbon to produce the satellite lines. The elements here in combination with the carbon are supposedly hydrogen and oxygen. It can be shown that the fre-

quency differences between the principal line and the various satellites are at least in qualitative agreement with this idea. There is also an agreement between the number of satellites observed and the number predicted from this consideration.

BORON

Boron lines were secured on 25 plates using boric acid, borax or boron on the anticathode. Fifteen of these lines were suitable for use in the densitometer. Second order boron overlapped the third order carbon line so that only the first order of boron could be measured.

The anticathodes of the boron compounds were prepared by fusing the compound on the anticathode. The line of pure boron was obtained by placing amorphous metallic boron obtained from Kahlbaum in a net-work of slots on the face of the anticathode.

Fig. 6. Densitometer curve of a boron line taken with fused boric acid.

Fig. 7. Densitometer curve of a boron line taken with fused borax.

Under visual observation the $K\alpha$ line of boron appears as a continuous band broader than that of carbon. In several cases with small glancing angles the line appears to be just resolved into a doublet. The maximum of the line in general is on the short wave side. Two attendant lines on each side of the boron line are also visible to the eye in the spectra of boric acid and of borax. These attendant lines are absent in the spectrum of pure boron. This point was investigated carefully and plates from pure boron were obtained with lines even denser than the lines of the compounds with however no trace of satellites.

For given conditions of exposure the more intense lines of boron were obtained at higher voltages. Most of the lines of boron were obtained at 2300 volts more.

Fig. 6 shows a densitometer curve of a boron line taken with fused boric acid. This curve was resolved into components in a manner similar to that described for carbon. Fig. 7 is the plot of a line taken with fused borax on the anticathode. The conditions under which these plates were taken and the values of the resolved components are given in Table II

TABLE II.

Plate No.	Material	Voltage	Plate Distance	Wave-lengths of components of boron													
				66.43	67.37	68.28	69.30	70.30	71.63	72.67	73.26	73.90	75.00	76.60

114	"	1800	40		67.76	68.38	69.45	70.30									
Averages				64.68	65.45	66.55	67.61	68.38	69.33	70.36	71.32	72.03	73.20	74.00	74.95	76.75	

No marked difference is observed between the fine structure of the borax lines and the boric acid lines. The densitometer curves of pure boron are shown in Figs. 8 and 9. It is seen that but four components remain in the lines in this case. It would appear, therefore, that the presence of the attendant lines may be due to the association of the boron with other elements.

The curve of Fig. 8 is for a line taken at 2300 volts while Fig. 9 shows a curve of a line taken at 1800 volts. As in the case of carbon, a definite shift of the maximum to the short wave side occurs with increasing voltage. Reasoning in a manner similar to that used in selecting the wave-length of the $K\alpha$ line of carbon it would appear justifiable to assign a wave-length 69.33A to the $K\alpha$ line of boron.

The results in Table II seem to show that there are 13 components in the lines obtained from the boron compounds located at 64.68, 65.45, 66.55, 67.61, 68.38, 69.33, 70.36, 71.32, 72.03, 73.20, 74.00, 74.95, and 76.75A and that the spectrum of the K -radiation of the boron used contains four components at 67.61, 68.38, 69.33 and 70.36A. All of these figures are uncertain in the second decimal place.

Fig. 8. Densitometer curve of pure boron line taken at 2300 volts.

Fig. 9. Densitometer curve of pure boron line taken at 1800 volts.

It should be noticed that although the amorphous boron was "metallic" undoubtedly it contained appreciable percentages of oxide, hydride and probably nitride.

The explanation of the fine structure through the hypothesis of the development of addition and subtraction quanta through the interaction of the boron radiation with excited or neutral atoms associated in the molecular lattice is more difficult than for carbon. If we accept these results as showing that the K -radiation of boron is composed of four components, then to predict the fine structure of the compounds of boron on the above hypothesis, it is necessary to calculate these addition and subtraction quanta for each of the four compounds. Boron is associated with oxygen in fused boric acid and with sodium and oxygen in fused borax.

These calculations being carried out the number of satellites predicted is found to be substantially the same as the number observed. Also in many cases a close concordance between predicted and observed wave-length is found. However, due to the fact that the lines predicted due to sodium are in all cases coincident within 0.1A with oxygen lines or original component lines no definite conclusions can be formulated at this time.

There can be no doubt that these attendant lines are associated with the $K\alpha$ of boron. They do not seem to be due to any other element. In no case was it found possible to secure the attendant lines in the absence of the boron line. It is of some significance that in every case where the attendant lines appeared the oxygen line was present also.

OXYGEN

The $K\alpha$ line of oxygen appears on all plates of the boron compounds and on many others. Although several densitometer curves were taken of this

Fig. 10. Densitometer curve of a typical oxygen line.

Fig. 11. Densitometer curve of the lines of beryllium.

line, only a single component appeared. Fig. 10 shows a curve of a typical oxygen line. The wave-length assigned to $K\alpha$ oxygen is $23.77 \pm 0.06\text{Å}$.

BERYLLIUM

A target of pure beryllium obtained from the Beryllium Company of America was used in the measurements of this element. Only faint traces of the presence of a line with three components could be obtained at 1800 volts using currents as large as 150 milliamperes for six hours. At 2700 volts beryllium lines of more intensity could be obtained using 40 milliamperes for two and a half hours. The line appears as a broad band with two distinct maxima. On the short wave side of this band a distinct line appears of the same intensity as the band.

Fig. 11 shows a densitometric curve of the lines of beryllium. Only four plates have been taken of this element of which three are suitable for use in the densitometer. It is not believed to be justifiable, therefore, to deduce values for the fine structure of the lines, but only for the three principal peaks. These maxima occur at $107.2 \pm 0.4\text{Å}$, $113.2 \pm 0.3\text{Å}$ and $118.7 \pm 0.2\text{Å}$. The great breadth, approximately 15Å , of this line is peculiar to this element and should be remarked.

DISCUSSION

It will be observed that the value we obtain for oxygen ($23.77 \pm 0.06\text{Å}$) is in good agreement with the value found by Söderman ($23.77 \pm 0.08\text{Å}$). Our value for beryllium ($113.2 \pm 0.3\text{Å}$) also checks with Söderman's value (113.4 ± 0.3) measured to the easily distinguishable maximum of this line.

The method of measurement used in our work in which a single component is selected from a group would seem to explain the divergence of our values for carbon and boron from those obtained by other investigators. Thus a visual measurement to the middle of the carbon line yields a value of 44.65A, in good agreement with the value of Söderman (44.70) and of Howe (44.62). The value (45.33) however, which we have finally selected based on a study of the components agrees very closely with the determination of Weatherby (45.4A). Similarly in the case of boron, a visual measurement to the middle of the line gives 67.8, in good agreement with Söderman's value ($67.80 \pm 0.2A$) and with that of Thibaud (68.0A) while the value here selected for the principal maximum is considerably higher, namely 69.33A.

The great breadth of the carbon, boron and beryllium lines must be accepted as a real effect, for the $K\alpha$ line of oxygen at 23.77A and the N doublets of tungsten at about 56A and 60A are fine lines.

In conclusion the author wishes to thank Dr. B. B. Weatherby who aided him in beginning this work. And especially does the author wish to express his thanks to Dr. C. B. Bazzoni under whom this work was carried out and whose many helpful suggestions and keen interest are largely responsible for the success of these measurements.

THE SPARK SPECTRA OF SILVER AND PALLADIUM
(Ag II AND Pd II)—AN EXTENSION

BY H. A. BLAIR

PALMER PHYSICAL LABORATORY, PRINCETON, N. J.

(Received June 9, 1930)

ABSTRACT

An attempt was made to excite the $4f$ electron spectrum of Ag II in the Schüller tube with helium. Failure is discussed assuming the excitation process Ag normal atom + He⁺. Some little extension was made to the lower spectrum. The Schüller tube was also used to extend the $4d^36s$ and $5d$ configurations of Pd II. About forty terms were added. A complete list of lines arising from high levels is given.

AG II

AN ATTEMPT was made, using the Schüller tube, to excite the spectrum connected with the $4f$ electron in Ag II. By Hund theory this should consist of the set of terms 3 and 1P , D , F , G , H in combination with the terms associated with the $5d$ electron. From analogy with other spectra the lines should lie in the lower half of the visible spectrum. Some fifty lines were measured in this region which could be allotted to the Ag II spectrum with reasonable certainty, but comparatively few were strong. About one quarter of these correspond to lines given in Kayser's Handbuch without displacement of wave-length. This lack of displacement further identifies these lines as being due to transitions from the $4f$ state for the following reason:—As is well known the lines due to transitions from high levels, which are diffuse when excited in the electric spark, are sharp when excited in the Schüller tube and besides have greater wave numbers by about two units. This means that the levels from which they arise are displaced by that amount toward their series limits. Since, however, the $4f$ levels will likely have a displacement similar to that known in the $5d$ it is to be expected that the lines due to transitions between them will not be displaced.

Among the lines observed some of the $5d$ differences were found, but it was not possible to identify any of the $4f$ terms with certainty on account of the fewness of the combinations. It appears that the Schüller tube is not well adapted to the excitation of this spectrum. This will be considered later in connection with the results in Pd II as well.

The spectral region from 2000 to 3000 Å which contains the lines of existing classifications of the silver spark, the most recent of which is due to Shenstone,¹ was also measured from Schüller tube plates. Shenstone's classification included all the predicted terms arising from the structures d^35s , $6s$, and $5d$, but the terms $5d^3P_0$ and $5d^1S_0$ were doubtful. The present measures gave about twenty new lines, some of which permitted these terms to be determined more reasonably, although the 1S_0 is much higher than expected

¹ Shenstone, Phys. Rev. 31, 317 (1928).

TABLE I. *Ag II terms.*

$d^9 5d^3 P_0$	89366.9	$d^9 5d^1 S_0$	95287.5
----------------	---------	----------------	---------

These new terms are given in Table I. To correspond with the other terms as previously given by Shenstone about 2 cm^{-1} should be subtracted.

In Table II are given the new lines as well as the few old ones whose allocations have been changed. In each case the wave number and wavelength are from Schüller tube measurements. From each of these also should 2 cm^{-1} be subtracted that they may fit Shenstone's terms. In the case of the old lines the authors and intensities are given.

Some of the previously classified lines were greatly enhanced with the Schüller tube. These are $\lambda 3372$ from 1 to 50, $\lambda 3269$, 1 to 40, $\lambda 3223$, 3 to 40, $\lambda 3184$, $1u$ to 50, $\lambda 3129$, $1u$ to 20. No reason can be given for these marked changes of intensity. The remainder of the lines in the group to which they belong, the $6s$, although in most cases stronger, were not greatly different.

Pd II

The spectrum arising from the electron configurations $4d^9$, $4d^8 5s$ and $5p$ of Pd II has been very completely analyzed by Shenstone.² He was also able to classify a considerable number of the diffuse lines giving several of the $4d^8 6s$ and $5d$ terms. The present work is an extension of the analysis of the lines arising from the latter configurations.

Method of excitation. As with the silver, the Schüller tube was used for the excitation of the spectrum. The cathode used in each case was cylindrical, open at both ends, and measured 0.5 inches in diameter, and 1.5 inches in

² Shenstone, Phys. Rev. **32**, 1 (1928).

length. Helium was used to carry the current. It was purified by continuous circulation through a Misch metal discharge, and through chabazite cooled with liquid air. All gaseous impurities but hydrogen were soon removed by this method. A current of about 200 m.a. was used, the line voltage being 750 d.c. The gas pressure was kept between 3 and 4 mm, a much lower pressure, i.e., about 2 mm being found, as usual, to give the spark spectrum weakly compared with the arc. The photographs were made with the Hilger E1 quartz spectrograph. The extent of excitation is discussed later.

The data. In Table III is given a list of all the lines obtained, both classified and unclassified. The unassigned lines were included since the accuracy of measurement is probably sufficient to render a repetition of the

a—weak in arc.

Wave numbers measured, wave-lengths calculated.

 I_1 —Meggers' intensities except for Shenstone's lines. I_2 —Author's estimates from Schüler tube.

Author—Original observer.

work unnecessary. The standards used were the corrected Pd II sharp lines from Shenstone's classification. In general no greater variation than 0.5 cm^{-1} was necessary in satisfying the combination principle with new terms. All the normally diffuse lines were included, even when they had been previously given by Shenstone, since the accuracy of measurement is here much greater, since some of the classifications have been altered and since the usual displacement of the diffuse lines by $2\text{--}3 \text{ cm}^{-1}$ prevents a consistent scheme. The complete line list of Pd II is obtainable by adding that here given to that of Shenstone's sharp lines.

TABLE IV. *Origin of high terms of Pd II.*

Config.	Pd III Term	Added Electron	Theoretical	Terms	
				Empirical	
$4d^8$	3F	$6s$	$^4,^2F$	$6s^4,^2F$	
		$5d$	$^4,^2P, D, F, G, H$	$ed^4 D, F, G, H$	parts of
	3P	$6s$	$^4,^2P$	$6s^4,^2P$	parts doubtful.
		$5d$			None identified.
	1S	$6s$			None identified.
		$5d$			None identified.
	1D	$6s$	2D	$6s^2D$	
		$5d$	$^2S, P, D, F, G$	jd	Not nameable.
	1G	$6s$	2G	$6s^2G$	
		$5d$	$^2D, F, G, H, I$	$gd^2D, F, G.$	

In Table IV are given the electron configurations of the high terms, the predicted terms and those thought to have been found. The lettering corresponds to that in the list of high terms given in Table V. Where a term could not be reasonably placed in a group it was left unlettered.

The $6s$ group. It was found possible to complete the $6s$ group satisfactorily, except for the $^2P_{\frac{1}{2}}$ term, and possibly the $^4P_{\frac{1}{2}}$ term, the former being particularly doubtful, as it requires the crossing over of the components of the doublet.

The convergence of the terms is odd in part. The $^4F_{4\frac{1}{2}}$ $^4F_{3\frac{1}{2}}$ separation has decreased from 2013.3 to 692.2 in going from the $5s$ to the $6s$ group, and these terms appear to be approaching the same limit as would be expected with the inverted type of convergence pointed out by Shenstone,^{3,4} i.e., where equal J values do not cross. The $^4F_{2\frac{1}{2}}$ and $^2F_{3\frac{1}{2}}$ however, which are also expected to have the same limit have already crossed over each other, although just by one cm^{-1} . It would be interesting to find what would happen in the next series member as well as to investigate the "strong field" Zeeman pattern of the present one. The lines are too diffuse to do this with a source in air, but it might be accomplished at low pressure. The $^4F_{1\frac{1}{2}}$ and $^2F_{2\frac{1}{2}}$ have converged considerably, again as expected. The doubtful validity of two of the P terms renders a discussion of their convergence profitless. The 2D has converted from -1227.2 to -612.9 while the 2G which in the first member had an interval of only 108.2 has closed to 12.5. The indication is that each doublet is going to its own limit.

The 5d group. The terms built on the $d^8\ ^3F$ of Pd III should be found in three groups with separations similar to those of the components of the 3F . This 3F of Pd III has not been found, but the $d^8s^2\ ^3F$ of Pd I which is known should have separations of about the same magnitudes. Its intervals are 3100 and 1500. The terms here designated "*ed*" which are considered to be those built on the 3F of Pd III are sharply divided into but two groups. The second group does in fact start at about 3,000 above the first but it shows no definite division within itself. This is to be expected, however, considering the narrowness of the interval.

The lower "*ed*" group which is quite distinct, which shows the proper quantum numbers to be based on the 3F_4 , and in which the naming of the terms was possible from intensities of combination is composed entirely of quartets of high inner quantum numbers. This apparent separation of the quartets and doublets seems to indicate the inverted type of convergence. In Ni I Russell⁵ found this situation with the quintets and triplets of the $d^8s\cdot 4p$ configuration, but it was not general throughout the spectrum.

The combinations made by the remainder of the "*ed*" group indicate a coupling in which the L vector is losing its identity. The "*fd*" group which is quite probably based on the 1D of the ion from its position, had to be left nameless also for this reason. The "*gd*" group gave much more complete combinations, and these terms could be assigned L values quite definitely. The "*gd*" 2H and 2I could not be found although the 2H at least should make sufficient combinations. It is noteworthy that the "*gd*" group lies at about 19,000 above the beginning of the "*ed*" just as does the $5s^2G$ above the $5s^4F$.

The unassigned lines. The type of coupling makes it difficult to find new terms by the method of differences as the expected differences frequently do not occur. The labor involved in a method of trial of lines is probably not warranted until more idea of the positions of the missing terms can be obtained. The several unassigned strong lines are quite likely due to missing terms of high L and J whose combinations will be very few.

Excitation limit with helium. The extent of excitation of these two spectra and the points of maximum excitation are in agreement with the discussion of these points by R. A. Sawyer.⁶ He has found that with metals of high melting point as cathodes where the presence of the atoms of the cathode substances in the discharge is due to sputtering rather than vaporization, that the principal processes of excitation start from the normal state of the atom. Thus the highest levels excited to any great extent will be those which lie at the energy of the helium ion, 24.48 volts, 198,290 cm^{-1} above the normal state of the metal atom. Further, there should be an intensity maximum at this energy as well as at 19.75 volts, the metastable potential of helium. Neither of the spectra here considered was measured in the region where the excitation maximum due to the metastable potential would occur, but they may be considered as regards the energy of the helium ion.

⁵ H. N. Russell, Phys. Rev. 34, 821 (1929).

⁶ Sawyer, Bulletin, Am. Phys. Soc. 5, No. 2, Abstract 22, April (1930).

In the case of silver the lowest term of the ion $d^{10} {}^1S_0$ is at $-39,163.9 \text{ cm}^{-1}$ from the $4d^9 5s {}^3D_3$ which has been used as the zero level. The ionization potential of Ag I is $59,370 \text{ cm}^{-1}$. Subtracting these energies from that of the helium ion leaves about $99,750 \text{ cm}^{-1}$ available for excitation, on the scale used. This is much too low for the $4f$ electron levels which from analogy with other spectra are to be expected to lie about $20,000 \text{ cm}^{-1}$ above the $5d$, i.e., at about $110,000$.

In the case of palladium the lowest term $4d^9 {}^2D$ is at $-25,081 \text{ cm}^{-1}$, while the ionization potential of Pd I is about $67,060$. About $106,150 \text{ cm}^{-1}$ is thus available for excitation, and there should be an intensity maximum of the lines arising from terms in this neighborhood. The " gd " doublet terms at $104,000$ do in fact give rise to the group of lines which, compared to the ordinary spark, is enhanced most in intensity and which is quite as strong as even the lowest of the high set of terms. Nothing can be said about the limit of excitation as no higher spectrum than the $5d$ was sought, and it is probably just within the available energy.

The author wishes to express his thanks to Professor A. G. Shenstone, under whose direction the work was done, and to the Carnegie Foundation through whose generosity the laboratory was enabled to procure a calculating machine which greatly facilitated the calculation of the wave-numbers from the measurements.

THE RESONANCE (*B-A*) BAND SYSTEM OF THE HYDROGEN MOLECULE

BY HUGH H. HYMAN
PHYSICAL LABORATORY, UNION COLLEGE
(Received June 3, 1930)

ABSTRACT

Part I. Experimental procedure. A three meter focal length vacuum spectrograph, designed by Professor J. J. Hopfield, has been constructed at the University of California and used to photograph the extreme ultraviolet hydrogen band spectra. A description of the type of mounting and method used to focus the instrument is given. The greater dispersion and resolving power has made possible the measuring of additional lines. New tables of frequencies are given.

Part II. Lines in sixty-eight bands have been given quantum assignments. On the basis of the old quantum theory the moment of inertia of the hydrogen in the normal (*A* level) state is found to be 0.4673×10^{-40} g cm² and the nuclear separation to be 0.7500×10^{-8} cm. In the first electronic excited state (*B* level) the moment of inertia is 1.4225×10^{-40} g cm² and the nuclear separation 1.308×10^{-8} cm. Comparison of the present results with those obtained by Richardson and Davidson in their study of bands found in the visible leaves no doubt but that the ultraviolet *B* state also is the lower state of the bands studied by them. This, then, verifies the assumption made by Birge and leads to the conclusion that the ionization potential of H₂ must be 15.34 volts to within a few hundredths of a volt.

Bands connected with vibrational levels *A*₀, *A*₁ and *A*₂ are not observed. In order to obtain the best possible value of *I*₀, data from all available sources were correlated and averaged. Birge and Jeppesen calculated accurate values of *B*₀ and *B*₁, for the normal level, from Rasetti's data on the Raman effect of gaseous hydrogen. Values for *B*₁ by the two methods agree to one part in seven thousand but their value for *B*₀ is 0.27 percent higher than the value given by the present method. This discrepancy points to an irregularity in the moment of inertia of hydrogen in the *v*=0 state of the normal electronic level, as has been pointed out by Birge and Jeppesen.

INTRODUCTION

INVESTIGATIONS of the fine structure of bands found in the extreme ultraviolet have been handicapped greatly by the low dispersion and resolving power of the instruments used in the photographic work. Professor J. J. Hopfield of the University of California has designed a vacuum spectrograph using a three inch grating, 15000 lines per inch, with a three meter focal length. It has been found that the instrument has a resolving power of 0.1Å and a dispersion of 2.76Å per millimeter in the second order. The spectrograph has been built in the shop of the Physics Laboratory of the University of California by Mr. W. R. Stamper and his assistants, following the plans furnished by Professor Hopfield.

The hydrogen bands of the extreme ultraviolet were photographed by the writer, this being the first vacuum work completed on the instrument.

Previous to the present work Dieke and Hopfield,^{1,2} by obtaining ab-

¹ Dieke and Hopfield, Zeits. f. Physik 40, 229 (1926).

² Dieke and Hopfield, Phys. Rev. 30, 400 (1927).

sorption and emission spectrograms, were able to give a complete analysis of the vibrational levels of the three known lower electronic states of the hydrogen molecule. These three states are known as the *A*, *B*, and *C* levels, the *A* level being the normal state of the molecule.

Schumann,³ Lyman,⁴ Witmer,^{5,6} Werner,⁷ Hori,⁸ and others had photographed and measured H_2 bands in the extreme ultraviolet. The bands photographed and measured by Werner constitute the *C-A* system, as given by Dieke and Hopfield. The Lyman-Witmer bands now are known to form the B_3-A_v transitions of the *B-A* system. These B_3-A_v bands are obtained when the discharge tube is filled with a mixture of argon and hydrogen. These same bands appear when only hydrogen is used in the tube, but generally are weaker, some of them being almost completely blended by more intense bands of the *B-A* system. Richardson, and his students,⁹ in a series of papers, have identified a great number of electronic levels of the hydrogen molecule. Birge¹⁰ assumed that the lower level of the Richardson "*A*" and "*B*" band systems¹¹ was identical with the *B* state of the bands in the ultraviolet. With a Ritz formula for the Richardson band system, Birge found the ionization potential of H_2 to be 15.34 volts. In the same paper a summary of the quantum levels and constants of the hydrogen molecule is given. Starting with the vibrational analysis as given by Dieke and Hopfield,^{1,2} Hori⁸ has obtained an analysis of the fine structure of the *C-A* bands. In the same paper he gave a preliminary analysis of the Lyman-Witmer progression (B_3-A_v), based on the assumed presence of *R*, *Q*, and *P* branches. For the latter work Hori used Witmer's measurements.

PART I. EXPERIMENTAL PROCEDURE

The instrument designed by Professor J. J. Hopfield and used for obtaining the spectrogram shown in Fig. 2 is so made that it is possible to obtain on the photographic plate any region of the spectrum. The plates are of such size that a span of 1200 Angstroms, in the first order can be photographed with one exposure. Arrangements have been made so that thirteen exposures may be taken on one plate. However, it has been found that limiting the number to five is more practical.

Type of mounting.

As the space to be evacuated needed to be kept a minimum, a modified form of the Eagle mounting¹² was used, instead of the Rowland type. The

slit, the photographic plate, and the grating were all placed in a cast iron tube three meters long. Five sylphons served as a means for making the adjustments of the plate-holder and grating. These adjustments could be made after a vacuum had been obtained. A grating to be used in this manner must be capable of motion along the tube, and also of rotation about a vertical axis. Fig. 1A shows how this was accomplished. The grating is fastened to the carriage *C* which is mounted on the rails *R*. Rods *D* and *E* served to move the grating.

The position of the grating is shown by two dials placed at *A* and *B*. The plate-holder *F-G* is pivoted such that the line of rotation passes through the line of the slit and the radius of curvature of the holder is one-half the radius of curvature of the grating. The slit is at *S*.

Fig. 1. Diagram of apparatus.

It is well known that in order to obtain the best definition with a concave grating the slit and the grating must be on a circle whose diameter is equal to the radius of curvature of the grating, and, in this case, all the spectral lines are focused on this same circle. The method of mounting fulfills these requirements. It can be seen that the exact position of four variables must be determined to obtain the focus.

Adjustment of the instrument.

The first work to be done was to focus the instrument for all regions of the spectrum. In the case of the Rowland mounting there is a standard method of procedure but in the mounting considered here the method is not so well established.

The first step in the adjustment was the leveling of the grating so that the images would all fall upon the horizontal opening over the plate. Once this position for the grating had been determined, this variable was eliminated.

The second step in the adjustment was to find the approximate settings of the plate, the grating, and the slit with respect to one another, for a definite region of the spectrum.

For convenience, a portion of the visible spectrum of the mercury arc was used. For approximate settings, the eye was used to examine the image

which was assumed to be formed on a photographic plate. When the adjustments were found sufficiently close to serve as a starting point, a photograph of the known lines of mercury was taken and examined for the purpose of determining the course of procedure. Upon examining these plates it was found that certain parts of the spectrum were in much better focus than others. This indicated that the angle of the plate-holder was not correct.

The question, then, was one of determining what changes were necessary in order to bring in focus all the spectrum that fell on this plate. This necessitated the determination of the angle of the plate, the angle of the grating and the distance of the grating from the slit.

To obtain these relations, the central part of the grating was covered. By covering the central part, each individual line appears as double, if not in focus.

With the central portion of the grating covered, photographs were taken and the doubling of the lines observed. At least three exposures were taken on one plate with the plate-holder fixed, the grating being moved along the tube.

One of these exposures was taken at what was considered the best focus for some part of the plate, and the other two on opposite sides of this point. On at least two of these exposures doubling occurred. By carefully measuring the distance between these doubled lines and then drawing graphs, the position of the grating for the focus of the line being considered was found. At least two lines on the plate, preferably at extreme ends, were used and from data obtained the position of the grating for the focus of a line that would fall on the slit was calculated. To determine the amount of rotation of the plate it was necessary to know, in addition to the above, the pitch of the screw that moved the grating and also the distance of the lines on the plate from the slit. It must be remembered that the focus moves in and out twice as fast as the grating moves.

If P_0 is the position of the grating for focus on the slit, P_a the position for the focus of the line being considered, k the pitch of the screw moving the grating, and d the distance of the line from the slit, then the grating must be moved approximately

$$\frac{2k(P_a - P_0)}{d} \times 57 \text{ degrees.}$$

By repeated trials the angle of the plate was determined as well as the position of the grating in the tube. Thus the four variables were determined that fixed the focus for the one region. This same process was repeated for each section of the spectrum. Allowance has been made for sufficient overlapping from one region to another.

After obtaining the focus from $\lambda 1000$ to $\lambda 6000$, photographs of the iron arc were taken ($\lambda 2300$ to $\lambda 6000$) and many of the lines identified and marked on the plates. These plates are on file for use as an easy method of identifying the exact region given by any one position.

Vacuum technique.

Perhaps one of the greatest difficulties to be overcome was the obtaining of a vacuum suitable for photographic work in the ultraviolet. The volume to be evacuated was approximately one hundred eighty liters. The surface of the iron pipe alone was over two and three-quarters square meters. The ends of the spectrograph were sealed with rubber gaskets and held firm by heavy bolts. The opening for inserting plates was sealed in the same manner. Five sylphons, three windows and two outlets also were potential sources of trouble. Several holes were found in the casting.

At first one mercury vapor pump backed by a large General Electric Company vacuum pump was used to evacuate the system. It was found that this was inadequate. A second mercury vapor pump was then inserted in parallel with the first.

The pressure inside the spectrograph under working conditions varied between 0.005 mm and 0.010 mm of mercury, as measured by a McLeod gauge.

Photographic work.

A π -shaped discharge tube, made of Pyrex with aluminum electrodes, was used. As the region photographed reached beyond the limit of transmission of quartz or fluorite, the discharge tube was fastened directly to the spectrograph. Current from a 11,500 volt transformer was used, and a water rheostat in series with the tube was so adjusted as to give a maximum of intensity without melting the tube. Approximately 0.5 of an ampere was run through the tube. Considerable difficulty was found in eliminating the continuous spectrum found when exposing the plate in the second order, but by grinding the inside of the tube until a rough surface was obtained, much of the continuous spectrum was found to disappear.

The hydrogen was generated electrolytically, passed through a drying tube of P_2O_5 , then through a capillary leak directly to the discharge tube. As the gas was being removed by a Cenco pump and also through the slit, it was necessary to have a continuous flow of hydrogen.

The evacuating pumps and the flow of hydrogen were started at least two hours before the photographic work, thus insuring a thorough flushing out of the discharge tube. Any trace of air was noticeable at once in the visible spectrum. The best plates obtained show no trace of known impurities. Schumann plates made by Hilger Company were used.

To make sure that no first order hydrogen lines were being photographed the discharge tube was run under the same conditions as were used for the good plates except that a quartz window was placed between the slit and the source of light.

In general, investigators in the extreme ultraviolet have been handicapped not only by low dispersion and low resolving power, but also by lack of suitable standards. As the measurements in this investigation were from plates showing the second order H_2 lines it was found possible to measure them using first order iron arc lines as standards.

An iron arc (see Fig. 1B) was used as the source of light for the comparison spectrum. The lens and the window shown were of quartz. The iron arc was run for five minutes before starting the hydrogen source and also for five minutes after stopping the discharge, thus enabling one to detect any shift in the lines while making the exposures.

Fig. 2.

The shutter over the plate was so arranged that by turning a screw the iron lines did not cover all the plate that had been exposed to the hydrogen light. The iron lines may be seen in Fig. 2 and are easily distinguished from the hydrogen lines. On the same plate is found also an exposure showing only hydrogen lines.

Only plates that showed no displacement of the iron lines were used for measurement. It was found that the instrument was very sensitive to temperature changes. No special provisions had been made for maintaining a constant temperature, but care was taken in keeping the room as nearly as possible at one temperature while making the exposures.

Many iron lines suitable for standards were found between 2600A and

3300Å.¹³ For the H₂ lines below 1300Å, hydrogen lines were measured in the third order against iron lines as standards and these hydrogen lines were then used as standards in the second order. The iron lines used as standards were spaced approximately 100Å or less apart.

The measurements were made on a 200 millimeter comparator purchased by Professor R. T. Birge through the generosity of the Rumford Grant Committee of the American Academy of Arts and Sciences. It is believed that the measurements are in all cases accurate to approximately 0.05Å.

In general the lines listed were measured from two different plates.

Tables I and II give frequencies of the lines measured and intensities. Intensities are merely visual estimates. Table I also gives the quantum assignments as discussed in Part II.

TABLE II. *Frequencies of lines between $\lambda 1260\text{Å}$ and $\lambda 1640\text{Å}$ measured but not identified in this work.*

The focusing of the instrument was carried out in cooperation with Dr. C. A. Pulskamp, to whom the writer is indebted for his valuable aid in adjusting the instrument. The writer also wishes to express his thanks to Professor J. J. Hopfield, who suggested the problem and under whose direction the experimental work was started.

PART II. ROTATIONAL DATA

While the work on the fine structure of the hydrogen resonance bands was in progress Kemble and Guillemin¹⁴ published an article in which they concluded, on theoretical grounds, that the *B-A* system must consist of *R* and *P* branches only.

¹³ H. Kayser, and H. Konen, *Handbuch der Spectroscopie*, Vol. 7, (1924).

¹⁴ Kemble and Guillemin, *Proc. Nat. Acad. Sci.* **14**, 782 (1928).

Richardson and Davidson¹¹ have completed the fine structure analysis of certain bands found in the visible. It will be shown that there is a definite connection between this band system and the *B-A* system.

Schaafsma and Dieke¹⁵ have published rotational energy data, based on H_2 plates obtained by Dieke with Hopfield's 50 cm vacuum spectrograph at the University of California. The quantum assignments in the present paper were made entirely independent of their work. Data from their work have been used, with other data available, in calculating the moment of inertia of the molecule in the normal state.

Two brief accounts of the preliminary work on the *B-A* bands have been published in short articles to *Nature*.^{16,17}

The vibrational analysis as given by Dieke and Hopfield^{1,2} serves as a starting point for this work. All results are given in terms of the old quantum theory unless specified otherwise.

Verification of combination principle.

The lines of the three possible branches, *P*, *Q* and *R* of the usual quantum theory are defined as follows¹⁸

$$R_J = F'_{J+1} - F_J'' \quad (1)$$

$$Q_J = F_J' - F_J'' \quad (2)$$

$$P_J = F'_{J-1} - F_J'' \quad (3)$$

The *Q* branch is not observed in the *B-A* bands. Kemble and Guillemin¹³ have given as the theoretical reason for this that the *B-A* bands represent a transition from the $2^1\Sigma$ level to the $1^1\Sigma$ level.

From Eqs. (1) and (3) it follows¹⁹

$$R_J - P_J = F'_{J+1} - F'_{J-1} = 2\Delta F_J' \quad (4)$$

$$R_{J-1} - P_{J+1} = F'_{J+1} - F'_{J-1} = 2\Delta F_J'' \quad (5)$$

Eq. (4) shows that the values of $2\Delta F_J'$ may be obtained from any band if the *R* and *P* branches are known and the relative rotational quantum numbering of the lines has been found. The values of $2\Delta F_J'$ should be identical, within the limit of experimental error, for all bands of the *A* or n'' progression; that is, these values should be the same for all bands having the same upper level (*B*).

In the same manner, the values of $2\Delta F_J''$ should be the same for all bands having the same lower level. These facts are illustrated in Fig. 3.

¹⁸ R. T. Birge, Chapter 4, p. 144 of Report of Committee on Radiation in Gases, Molecular Spectra in Gases, Bulletin No. 57 of the National Research Council, (1926). This bulletin is referred to hereafter as the "Report." In general the nomenclature in this paper is that used in the Report.

¹⁹ Report, p. 145.

The combination principle was first verified by choosing three bands such that two have the same B level and two the same A level, and finding differences between R and P lines such that equations (4) and (5) were satisfied.

Fig. 3. Energy level diagram.

The vibrational analysis had been found by Dieke and Hopfield.² It was not necessary to know the true numbering of the lines in the bands. The method of obtaining this numbering will be explained later. The lines of the individual band were separated into R and P branches by the usual method of second differences.

After verifying the combination principle for these three bands, the work was extended to other bands. The results are collected in Tables I, III, and IV. Lines connected with sixty-eight bands were found. The results show alternating intensity of lines as is to be expected since the H_2 molecule is symmetrical.

To find m , the effective rotational quantum number, the $2\Delta F'$ values are plotted and extrapolated to $\Delta F=0$. m is now to be chosen so that ΔF equals zero when m equals zero and it is found that this condition is satisfied, at least to a close approximation, by assuming half integer values for m . Richardson and Davidson¹¹ referring to the lower level of bands analyzed by them, state " $m_0=0.50013$ and remains very close to $1/2$ throughout the vibrational levels." This level is now known to be identical with the B state as described in this paper.

Continuing the study of the B state later, it will be shown, by using the analytic method,²⁰ that the value of m is found to be a half-integer to

²⁰ Report, p. 173.

within 0.005, that is,²¹ α is zero or practically zero. At present we assume²² $m = k = J - 0.5$.

A second check on the assignment of the lines to the R and P branches was found by comparing the values²³ of $\omega_v(m)$ for the B level as obtained by

TABLE V. B -state. Average values of $\omega_v(m)$ (From both R and P lines). Values in parentheses are those obtained by Richardson and Davidson from bands in the visible.

ences of two frequencies neither of which was from blended lines were given weighted values. Fig. 3 also shows the values of $\omega_v(m)$. The numbers on this diagram are obtained by using P lines. Table V also gives (in parenthesis) the values as obtained by Richardson and Davidson¹¹ from their analysis of

²¹ Report, p. 137 gives $m = J - \epsilon^* = J - 0.5 - \alpha = k - \alpha$, where J is an integer and k a half-integer. This is in terms of the old quantum theory as used in this paper. In the new mechanics J is one unit less.

²² It is to be remembered that the value of $m - 1/2$ is the value of J for the new mechanics.

²³ Report, p. 113.

bands in the visible. The Richardson and Davidson measurements are from plates taken using a larger grating and the bands measured are in the visible. Their values of $\omega_v(m)$ are presumably the more trustworthy. It is to be remembered that an error of one-tenth Angstrom in the ultraviolet region considered here represents an error of between six and nine frequency units.

The values of $\Delta F'$ as obtained from the rotational energy function²⁴ also agree almost identically with those obtained by Richardson and Davidson from their data. They give a value of D_0 (their C) smaller than the theoretical value. The D_0 used in the present report is found theoretically and represents the best known method for obtaining this constant, while Richardson and Davidson have obtained the value empirically. More will be said about these constants later.

Birge¹⁰ in his summary of the quantum levels and resulting constants of the hydrogen molecule has taken the B state of the ultraviolet bands to be also the lower state of the Richardson "A" and "B" bands. This seemed justifiable at that time as the result of the close agreement of the vibrational data of Dieke and Hopfield² and of Richardson.¹¹

The far more accurate data of the present work confirms the assumption beyond all doubt, since the agreement of the spacings of all levels, both vibrational and rotational, is within the very small limits of experimental error. This verification of the assumption by Birge leads to the conclusion that the ionization potential of H_2 must be 15.34 volts to within a few hundredths of a volt, as given by Birge at that time.

Mention has been made of the rotational energy function

$$F = B_0 m^2 + D_0 m^4 + F_0 m^6 + \dots \quad (6)$$

It is from this equation that the actual spacings of the rotational energy levels are found. The value of B_0 is inversely proportional to the moment of inertia for no vibration and infinitely slow rotation.

Birge, in the Report,²⁵ gives three methods of handling the data obtained. Method one is purely empirical and is not to be considered here.

Method two is a rapid semigraphical method for evaluating B_0 .

From the rotational energy function, by assuming $m = k - \alpha$, one obtains, to a very close approximation when α is small.

$$\frac{\Delta F}{k} = 2B_0 - \frac{2B_0\alpha}{k} + 4D_0k^2 + 6F_0k^4. \quad (7)$$

In the present work α is zero, or at least very small. If we assume the value of F_0 to be small²⁶ we have

$$\frac{2\Delta F}{k} = 4B_0 + 8D_0k^2. \quad (8)$$

This equation represents a parabola with the vertex at $k = 0$.

²⁴ Report, p. 141.

²⁵ Report, pp. 169-173.

²⁶ Richardson and Davidson gave α equal to 0.0013, $F_0 = 1.3 \times 10^{-5}$.

The values of $2\Delta F/k$ for the B_0 state are

k	1.5	2.5	3.5	4.5
$\frac{2\Delta F}{k}$	77.60	77.16	76.09	75.11

These latter values were plotted against k and from this a fairly accurate value of $4B_0$ found directly.

D_0 is theoretically related to B_0 by the relation

$$D_0 = \frac{-4B_0^3}{\omega_0^2} \quad (9)$$

ω_0 is found by double extrapolation of the values of $\omega_v(m)$ to find the value of $\omega_0(0)$.

The final result of this extrapolation is that $\omega_0(0) = 1337.82 \text{ cm}^{-1}$.

Method three is strictly analytic and is the most accurate method of handling the data.

From the rotational energy function the following result is obtained, where $m = k - \alpha$

$$2\Delta F^* = 2\Delta F - 8D_0k^3 - 12F_0k^5 - 16H_0k^7 = (4B_0 + 8D_0)(k - \alpha) \quad (10)$$

if the values of F_0 and H_0 are zero.

The value of $2\Delta F^*$ may be called the reduced value of $2\Delta F$. The values of $2\Delta F$ are found directly. Values of F_0 and H_0 are assumed to be equal to zero. The value, $D_0 = -0.01647$, is found by using the approximate value of $B_0(19.46 \text{ cm}^{-1})$ found by method two in the theoretical Eq. (9).

In the equation $2\Delta F^* = 2\Delta F - 8D_0k^3$ the following values are found:

$2\Delta F$	k	$8 - D_0k^3$	$2\Delta F^*$
116.4	1.5	0.4447	116.845
192.9	2.5	2.059	194.959
266.3	3.5	5.649	271.949
338.0	4.5	12.007	350.009

The plot of $2\Delta F^*$ against k is a straight line, as predicted by the above theory.

The least squares solution of the equation

$$2\Delta F^* = (4B_0 + 8D_0)(k - \alpha) \quad (11)$$

accordingly gives the most probable values of B_0 and of α .

The solution gives

$$B_0 = 19.445 \text{ cm}^{-1}; \quad \alpha = -0.005 \text{ cm}^{-1}.$$

It is believed B_0 has a true probable error not exceeding one part in one thousand. The probable error in α is such that the true value may be zero.

Richardson and Davidson have found $B_0 = 19.455_5$.

The moment of inertia is found from the relation

$$I_0 = \frac{h}{8\pi^2 B_0 c} = \frac{27.66 \times 10^{-40}}{B_0} \text{ g cm}^2 \quad (12)$$

$$= (1.4225 \pm 0.003) \times 10^{-40} \text{ g cm}^2.$$

The error in B_0 is also to be found in the value of the moment of inertia. In addition there is a small probable error in the constant²⁷ 27.66×10^{-40} . The nuclear separation r_0 , in centimeters, is given by the relation

$$r_0 = (I_0/\mu)^{1/2} \quad \text{where}$$

$$\mu = 1.6490 \times 10^{-24} \frac{m_1 m_2}{m_1 + m_2} \quad \text{and}$$

m_1 and m_2 are the atomic weights of the two atoms.²⁸

The resulting value for the nuclear separation is

$$1.3084 \times 10^{-8} \text{ cm.}$$

The rotational energy function becomes

$$F = 19.445m^2 - 0.01647m^4 \quad (14)$$

$$m = \frac{1}{2}, 1\frac{1}{2}, 2\frac{1}{2} \text{ etc.}$$

The following is a comparison of the values of F obtained with those given by Richardson and Davidson:

Richardson and Davidson from bands in visible	$B-A$ bands found in ultraviolet

In the solution, Richardson and Davidson have used $D = -0.0152 \text{ cm}^{-1}$ instead of -0.01647 .

Constants for the normal level.

The evaluation of the moment of inertia of H₂, for the normal electronic level, has been carried out with the cooperation of Mr. C. Rulon Jeppesen, and the results have been reported briefly.¹⁷ In this case the values of $2\Delta F''$, as given in Table IV, begin at the vibrational level $v = 3$. For $v = 0, 1$, and 2 , the less accurate and extensive data of Hori,⁸ and Witmer,⁶ were used. These

²⁷ Birge, Phys. Rev. Supplement 1, 63 (1929) gives

$$h/8\pi^2 c = (27.65_{33} \pm 0.04) \times 10^{-40} \text{ g cm.} \quad (13)$$

²⁸ Constants used are those given by Birge, reference 27.

data are listed in Table IVa. In order to obtain the best possible value of I_0 , data from all available sources were correlated and averaged. These sources include Schaafsma and Dieke,¹⁵ in addition to those already quoted.

The various values of $2\Delta F/k$, resulting from the observations of the different observers, were plotted against k , on a large scale. In this case Eq. (7) becomes

$$\frac{2\Delta F_v}{k} = 4B_v + 8D_vk^2 + 12F_vk^4 \quad (15)$$

and the resulting curve, for each value of v , should be approximately a parabola with its vertex at $k=0$. Smooth curves were drawn through the plotted points, so as to satisfy, roughly, the form of Eq. (15). From these curves we obtain first approximate values of $4B_v$. These values were then plotted against v , and found to form a reasonably smooth curve. What appeared to be the best smooth curve was then drawn, and from—this, smoothed values of $4B_v$ were obtained. These smoothed values were now used to calculate theoretical values of D_v , using the theoretical relation²⁹

$$D_v = D_e - \beta(v + \frac{1}{2}) \quad (16)$$

where³⁰

$$\frac{\beta}{D_e} = -\frac{\omega_e}{24B_e} \left(\frac{\alpha}{B_e} \right)^2 - 5 \left(\frac{\alpha}{B_e} \right) + 8x_e. \quad (17)$$

The value of $\omega_e(4368.6 \text{ cm}^{-1})$ was obtained from a smooth curve, using data by Witmer.⁶ Still later work³¹ has led to 4371 cm^{-1} as the best value of ω_e , but the change is immaterial in connection with β . For B_e we used 60.16 cm^{-1} , as obtained by extrapolating our smooth B_v curve to $v = -\frac{1}{2}$. The slope of this curve, at $v = -\frac{1}{2}$, gives the value of α (2.68 cm^{-1}).

We could now calculate theoretical values of $8D_vk^2$, in Eq. (15). In order to calculate the final term in Eq. (15), we assumed³² that

$$F_v = F_e = \frac{D_e^2}{B_e} \left(2 - \frac{\alpha\omega_e}{6B_e^2} \right) \quad (18)$$

The true theoretical expression for F_v , as a function of v , has not yet been derived, but the last term in Eq. (15) is so small that any change of F_v with v is immaterial, for not too large values of k .

²⁹ In this case, the new mechanics relations have been used. In equations like (9), one should use D_e , B_e , and ω_e (values for $v = -1/2$) in place of D_0 , B_0 , and ω_0 , but numerically the change is insignificant.

³⁰ This theoretical expression for β/D_e is equivalent to that given by Pomeroy (Phys. Rev. 29, 59 (1927)), but is much simpler in actual use. It was suggested to us by Professor R. T. Birge.

³¹ R. T. Birge and C. R. Jeppesen, Nature 125, 463 (1930).

³² Compare "Report," p. 237, Eq. (198).

With these calculated values of D_v and F_v , we now obtained a value of $4B_v$ from selected points on the $2\Delta F_v/k:k$ curve, using Eq. (15). A weighted average of the resulting values of $4B_v$, for each value of v , was thus obtained. This process is equivalent to drawing a smooth curve through the plotted $2\Delta F_v/k$ points, having the theoretical *shape*, leaving only the constant term to be evaluated. Such curves, as actually drawn, were found to be quite as satisfactory as the original empirical curves. This is a most gratifying verification of theory, since the "distortion" of the H₂ molecule, with both rotation and vibration, is relatively large.

The new values of B_v were again plotted against v , and found to lie much more closely on a smooth curve than the original approximate values. The changes were, however, so small that it was deemed unnecessary to calculate *new* theoretical values of D_v (method of successive approximations). Since we had used the *finite* differences $2\Delta F_v$, the value of the constant term in Eq. (15) is, strictly, not $4B_v$, but³³ $4B_v + 8D_v$. The final smoothed values of B_v , obtained after this correction, are given in Table VII. They were then fitted, by least squares, to a third degree rational integral function, the result being

$$B_v = 60.587 - 2.7938(v + \frac{1}{2}) + 1.0500 \times 10^{-2}(v + \frac{1}{2})^2 - 24.058 \times 10^{-4}(v + \frac{1}{2})^3. \quad (19)$$

TABLE VII.

v''	$B_{v''}$ smoothed observed values	$B_{v''}$ calc. values
0	59.19	59.192
1	56.415	56.411
2	53.63	53.630
3	50.835	50.834
4	48.01	48.008
5	45.14	45.138
6	42.20	42.210
7	39.20	39.209
8	36.145	36.120
9	32.92	32.930
10	29.52	29.624
11	25.39	26.187
12	20.565	22.606

The calculated values, according to Eq. (19), are also given in Table VII. In this equation, the absolute term gives the value B_e for the hypothetical state of zero vibration ($v = -1/2$), according to the new mechanics. It corresponds to $I_e = 0.4565 \times 10^{-40}$ g cm² and $r_e = 0.7412 \times 10^{-8}$ cm. This is quite different³⁴ from Hori's value of $I_e = 0.467 \times 10^{-40}$. The value of B_0 .

³³ See Eq. (145), p. 174 of "Report."

³⁴ See reference 17 for a discussion of this point.

corresponding to $v=0$, is 59.192 cm^{-1} , giving $I_0=0.4675\times 10^{-40}$, $r_0=0.7500\times 10^{-8}$. These latter are the constants for the actual normal level of hydrogen.

As already noted, accurate data for $2\Delta F''$ values extend only from $v=3$ to 12, inclusive (Table IV). As can be seen from Table VII, Eq. (19) fits the data in a satisfactory manner only up to $v=9$. In fact, the B_v values for $v=10, 11, 12$, were not used in obtaining this equation, since they deviate sharply from any smooth curve. These higher values of v are close to dissociation, and the fact that the corresponding moments of inertia are appreciably larger than those given by the equation is not surprising.

The values of B_0, B_1 , and B_2 are not so trustworthy, but they do, perhaps accidentally, fit in very well with the values B_3 to B_9 . It would therefore appear that our final value of B_0 is reliable to about 0.2 percent. After this work was completed, Birge and Jeppesen³¹ calculated accurate values of B_0 and B_1 , from Rasetti's data³⁵ on the Raman effect in gaseous hydrogen. Their value of B_1 (56.4035 cm^{-1}) is in remarkable agreement with our value of 56.411 cm^{-1} , as given by Eq. (19), but their value of B_0 (59.354 cm^{-1}) is 0.27 percent greater than our value of 59.192 cm^{-1} . This discrepancy points to a real irregularity in the moment of inertia of hydrogen in the $v=0$ state, as discussed by Birge and Jeppesen. They discuss also an apparent irregularity in the frequency of vibration for this same level.

The final conclusion is then that Eq. (19), or Table VII, last column, gives reliable values of B_v'' from $v=1$ to 9 inclusive, but that the true value of B_0 is that given by Birge and Jeppesen, namely $B_0=59.354\text{ cm}^{-1}$, corresponding to $I_0=0.4660\times 10^{-40}\text{ g cm}^2$ and $r_0=0.7489\times 10^{-8}\text{ cm}^{-1}$. Because of the irregularity in the value of B_0 , it is impossible to give a reliable value of B_v , but it seems best, in calculating theoretical values of D_v and other derived constants, to use the value given by Eq. (19).

The experimental work and part of the theoretical work, of this investigation, were carried out at the University of California and the writer wishes to express his sincere thanks to Professor R. T. Birge of the University of California not only for the very obliging and valuable assistance that was given while the writer was at the University of California but also for the interest and advice he has given during the past year. He is also indebted to Mr. C. R. Jeppesen for his help in deriving the constants for the normal level.

THE LUMINESCENCE OF ZINC SULPHIDE UNDER THE ACTION OF ALPHA, BETA AND GAMMA-RAYS

BY GEORGE S. GESSNER

RANDAL MORGAN LABORATORY OF PHYSICS, UNIVERSITY OF PENNSYLVANIA

(Received May 21, 1930)

ABSTRACT

The luminescence of zinc sulphide under the action of α , β and γ -rays was studied with an especially designed brass capsule. The zinc sulphide was exposed to the α -rays or β and γ -rays, or α , β and γ -rays from radium or its products, while the luminescent material and the exciting agent were kept separate. In this way the effect of these rays upon the luminescent material was observed, separately and collectively. The experiment was made under practically constant temperature. The luminosity time curves for the three types of capsules were consistent in characteristics. It was found that for a time there was a definite increase in brightness; then the luminescence decreased under the constant action of the rays and rose again to a second maximum. This was followed by gradual decrease with time as long as observations were taken. The decay of luminescence of zinc sulphide, after the removal of the radio active source, showed that the decay curve is not of the type whose ordinate can be expressed by a single exponential term.

INTRODUCTION

THE action of α , β and γ -rays from radium or its products, upon luminous compounds has been studied by several experimenters¹ during the last two decades and theories have been formulated to explain their results.

Przibram² and his students found that the luminescence of some minerals increased under the action of β -rays and then gradually decayed after passing through a maximum. Smith³ found an increase in brightness at room temperature of chemically pure barium bromide.

Studies in luminosity of luminescent zinc sulphide under the action of α , β and γ -rays from radium or its products, up to this time, have been made using mixtures of the luminescent material and the radioactive exciting agent. One of the features of the present research was to keep the radioactive source separate from the luminescent material, thus avoiding the possible formation of complex products. Another feature was the use of a source of radiation which remained constant during the period of the experiment. Thus it was possible to observe the brightness as soon as the luminescent material was brought in contact with the radioactive source. This was not done in previous experiments on zinc sulphide because of the

³ L. E. Smith, Phys. Rev. **28**, 431 (1926).

time taken for the source of rays to become constant. It was also thought desirable to use a strong source of radiation, hoping thereby to hasten the decay.

Not only were the radioactive source and the luminescent material kept separate but the luminescent material was kept inclosed in a capsule so that it could be studied before bringing it in contact with the radioactive source or after its removal.

APPARATUS AND PROCEDURE

In order to keep the luminescent material separate from the radioactive source, brass capsules were prepared, as shown in Fig. 1, each consisting of five major parts. On a gold plate fitted snugly in a depression on the face of part (5) was placed a layer of radium sulphate in equilibrium

Fig. 1. Brass capsule.

with its decay products and covered with a coat of varnish. Such a plate furnishes a constant source of radiation permitting the α as well as the β and γ -rays to pass through. Part (4), serving to hold parts (1) and (5) together consists of a thin brass washer to which are fastened several legs fitting snugly into holes in part (5). Part (1) is a brass washer to which can be fastened part (2), an aluminum washer; a thin sheet of mica is

TABLE I.

Capsule	Radium content	Rays emitted
1	0.293 mg	α β γ
2	0.522	α β γ
3	0.910	α β γ
4	0.815	α β γ
A	2.40	α β γ
B	.16	β γ
C	2.8	α β γ
D	Pol.	

placed between the brass washer and the aluminum washer and parts (1) and (2) are fastened together by means of small screws. The luminescent material was placed in the opening in the aluminum washer (2) and the sample as well as the aluminum washer were covered with a piece of very thin mica (3). Against this mica disk part (4) was fastened by means of small screws. Thus the sample was separated from the radioactive source and also protected from contamination by radium and its products.

Three different kinds of capsules were prepared: (A) where the mica disk (3) was thin enough to allow α as well as β and γ -rays to pass through (in some cases the mica was replaced by aluminum foil); (B) where the mica (3) was thick enough to allow only the β and γ -rays to pass through; (C) where the layer of radium sulphate was replaced by a polonium plate, giving off chiefly α -rays. Thus it was possible to study the effect of α -rays or β and γ -rays or α , β and γ -rays upon the sample of zinc sulphide.

The luminosities of the different samples were measured by means of a Nutting polarization photometer. The arrangement of apparatus is shown in Fig. 2. The apparatus is so arranged that by changing the distance between the standard lamp and the ground glass screen, its illumination of the screen can be controlled. The standard lamp *S* is supplied by means of storage batteries and its voltage maintained constant by a potentiometer arrangement, and a ballast lamp to stabilize the current for small variations in the battery voltage. Light from the standard lamp is reflected by the rhomb *R*, thus passing through the polarizing Nicol *PN* and the photometer cube *C*. Light from the sample *B* is reflected by the prism *D* thus passing into the photometer cube *C*, and is again reflected as shown in Fig. 2.

Fig. 2. Diagram of photometer.

In making an observation, the telescope is focused on the photometer cube and the field appears as two strips of reflected light from the sample *B* with the transmitted light from the standard lamp between them. By varying the intensity due to the standard lamp by means of the Nicol prism *AN*, the central strip is made alternately lighter and darker than the strips illuminated by the sample *B* until an intensity match is obtained. With the exception of the improvement in design of the capsule the apparatus is the same as that used by Smith³ in his study of barium bromide. The reference lamp *S* was a 110 volt incandescent carbon filament lamp operated at 60 volts. This lamp was compared with a lamp standardized by the Bureau of Standards. A green filter *F* was interposed to produce a better color match.

The brightness of the samples was readily calculated from the scale readings of the photometer and the constants of the apparatus. The photometer was graduated in logarithms of the ratio of the illuminating power of the standard lamp to that of the sample. If *K* is the transmission coefficient of the filter, *C*₁ the candle power of the standard lamp, *C*₂ the candle power of the sample, *d*₁ and *d*₂ their respective distances from the ground glass screen *G*,

$$\log_{10}(KC_1/d_1^2) - \log_{10}(C_2/d_2^2) = x \text{ (reading on photometer).}$$

If A is the area of the exposed luminous portion of the sample, the brightness B in apparent candle power per square cm is

$$B = (KC_1d_2^2)/(d_1^210^xA).$$

The sample of luminescent zinc sulphide approximately 0.020 cm in thickness was prepared and sufficient time allowed for the decay of the luminosity due to exposure to light in preparing. The sample was slipped on part (5) Fig. 1 and its luminosity read at intervals of a few minutes for the first hour, then at slightly longer intervals for the first day. All measurements were made at room temperature.

RESULTS

This study has shown that for crystalline zinc sulphide, there is first an initial growth to maximum value, then a decrease in luminosity followed by a second growth to a maximum, and then a very slow decay.

Fig. 3a. Luminosity curve, capsule (4), α , β , γ -rays. Zinc sulphide screen.

Figs. 3a and 3b show the variation of luminosity with time for two samples (4) and (A) (radium content given in Table I); from these curves will be seen that the maxima as well as the time required to reach these maxima are dependent upon the amount of radium present. Capsule (4) containing less radium than capsule (A) requires a longer time to reach the maximum values

Fig. 3b. Luminosity curve, capsule (A), α , β , γ -rays. Zinc sulphide screen.

and these maxima are lower time to reach the maximum values and these maxima are lower than for capsule (A). Similar results were found for capsules (1), (2), and (3). Capsule (1) for example, containing 0.293 milli-

grams of radium, required about 5 hours to reach the first maximum and about 15 hours to reach the second maximum. The maximum brightness for capsule (1) was 1.65×10^{-6} candle power per square cm. In all the above cases the sample of zinc sulphide was bombarded by α , β , and γ -rays.

Fig. 4 is a luminosity time curve for capsule (C). In this case the luminescent material was bombarded by β and γ -rays only. This curve also shows

Fig. 4. Luminosity curve, capsule (C), β , γ -rays. Zinc sulphide screen.

the two maxima but the time required to reach the first maximum value was about 20 minutes and the second maximum about 13 hours.

Fig. 5 shows the curves of Fig. 3a, 3b and 4 plotted over a longer period of time. From this curve we can see that the rate of decay for capsule (A) after reaching its second maximum is greater than that of capsule (4). The

Fig. 5. Curves of Figs. 3a, 3b and 4 plotted over long periods of time.

decay of capsule (A) was not nearly so rapid as was expected from consideration of the amount of radium present in the two cases. It must also be noted that decay of luminescence for capsule (C) (which emits only β and γ -rays) after reaching the second maximum is much slower than for capsule (A).

The initial part of the luminosity time curve for capsule (D) is shown in Fig. 6. In this capsule the radium sulphate was replaced by a polonium plate so that the sample of zinc sulphide was bombarded chiefly by α -rays. Here also is seen the initial growth, decay and second maximum, followed by a gradual decay.

Fig. 7 shows the variation of luminosity with time for capsule (4) over a period of 400 days. Only one maximum is shown on this curve, this is due to the small time scale used in plottings. From this curve and similar curves

Fig. 6. Luminosity curve, capsule (D), Po α -rays. Zinc sulphide screen.

drawn over long periods, it was found that the decay of luminosity was not hastened as much as was expected by using a strong radium source.

Fig. 7. Variation of luminosity with time for capsule (4) over a period of 400 days.

The theory of radioactive luminosity formulated by Walsh,⁴ in which the variation in brightness with time was expressed by the equation

$$\log \left[\frac{B}{(b + B)} \right] + a + kt = 0$$

where a , b , and k are constants, does not fit the observed decay curves of brightness found in this investigation.

Neither do the other theories mentioned by Walsh on radioactive luminescence explain the initial growth or the appearance of the second maximum, which was characteristic of all the curves plotted, whether the material was bombarded by α or β and γ , or α , β and γ -rays.

Since the luminescent material and the radioactive source were kept separate, it was possible to study the decay of the luminescent material after the radioactive source was removed. The screens containing the luminescent material were placed in contact with the exciting agent until the maximum brightness was reached and then the radioactive source was removed and the rate of decay of luminosity with time was studied. Fig. 8

⁴ J. W. T. Walsh, Proc. Phys. Soc. of London 39, 318 (1926-27).

shows the relation of brightness to time. The broken curve (with ordinates on the right) shows the relation between logarithms of intensity and time. From this curve it can readily be seen that the luminosity time curve, for a sample after the exciting agent was removed, is not of the type whose ordinate can be expressed by a single exponential term.

Fig. 8. Curve A = relation between logarithms of intensity and time.
Curve B = luminosity vs. time.

The fact that the decay of the zinc sulphide after removal of the exciting agent is not a single exponential may be an important factor in the formulation of a theory explaining the initial part of the brightness curves found in this investigation.

In conclusion the writer wishes to express his appreciation to Professor D. H. Kabakjian who suggested the problem, prepared the radium samples and under whose direction the work was carried out, and to Dr. E. E. Witmer for many helpful suggestions and discussions.

A SECOND IONIZATION POTENTIAL IN
POTASSIUM VAPOR

BY A. L. HUGHES AND C. M. VAN ATTA

WASHINGTON UNIVERSITY, SAINT LOUIS

(Received June 11, 1930)

ABSTRACT

The occurrence of a second peak in the photoionization curve of potassium vapor (Lawrence and Edlefsen) suggests that there might be a related peak (or discontinuity) in the curve for ionization by electron impact. The ionization in potassium vapor was investigated by Hertz' method of neutralization of space charge by positive ions. It was found that there was an abrupt increase in gradient of the ionization curve, indicating a second ionization potential at 0.97 ± 0.05 volt above the first one corresponding to the series limit. With mercury vapor, the apparatus indicated the presence of Lawrence's ultraionization potentials in mercury vapor, together with three new ones (10.40, 10.62, 10.88, 11.28, 11.40, 11.77, 12.16, 12.46).

INTRODUCTION

CERTAIN peculiarities in the photoionization curve of potassium in the vicinity of the series limit led to these experiments. Lawrence and Edlefsen¹ found that the photoionization of potassium is a maximum at the series limit (2856Å), diminishes to a minimum at 2700Å, and then rises to a second higher maximum at 2340Å. Mohler and Boeckner,² however, find that the ionization starts at the series limit and increases steadily. This curve resembles Lawrence's³ earlier results except for the fact that in the latter case the effect began at 2600Å. The peculiar form of the curve obtained by Lawrence and Edlefsen suggests that in ionization by electron impact something of a similar nature might be revealed. The only work which we can find on the ionization potential of potassium by electron impact is that done thirteen years ago by Tate and Foote,⁴ who identified roughly the ionization potential with the theoretical value corresponding to the series limit. They were interested only in establishing this approximate identity and made no attempt to study the shape of the ionization curve above the ionization potential. Another result which suggests that a careful study of the ionization curve for potassium might reveal peculiarities is Lawrence's discovery of the ultraionization potentials of mercury vapor (i.e., discontinuities in the ionization curve at 0.20, 0.89, 1.30 and 1.66 volts above the theoretical ionization potential corresponding to the series limit).

APPARATUS AND RESULTS

The method used for investigating the ionization potential was that originally used by Hertz. An oxide coated platinum filament, F , 11 mm long,

¹ E. O. Lawrence and N. E. Edlefsen, *Phys. Rev.* **34**, 1056 (1929).

² F. L. Mohler and C. Boeckner, *Bureau of Standards, Journal of Research* **3**, 303 (1929).

³ E. O. Lawrence, *Phil. Mag.* **50**, 345 (1925).

⁴ J. T. Tate and P. D. Foote, *Washington Acad. Sci. Jour.* **7**, 517 (1917).

was mounted in a rectangular box of monel metal, *B*, $25 \times 30 \times 15$ mm. A second oxide coated filament, *C*, was located just outside the box, opposite a small slit 0.6 mm in width. The slit was at right angles to the filament,

Fig. 1. Diagram of tube.

so that only those electrons coming from a nearly equipotential region of the filament, *C*, were allowed to enter the box. The potassium was dis-

Fig. 2. Arrangement of balancing circuit.

tilled into a side tube, *D*. The whole of the apparatus, including part of the tube leading to the pump, was surrounded by a furnace, the temperature of which could be controlled.

To measure the change in the space charge limited current from F , caused by ionization inside the box, we used a balance arrangement, shown in Fig. 2. The thermionic current from the filament, F , passed through a resistance R . The voltage drop across R was balanced by an opposing potential from the potentiometer, P , through the galvanometer, G . Any change in the space charge limited current, far too small to be measured

Fig. 3. Ionization curves for K vapor.

Curve:	I	II	III	IV
Temp.:	189	200	197	197°C

accurately on the micro-ammeter, M , could be easily read on the galvanometer. To secure steady conditions, batteries of large capacity were used.

In order that almost every electron from C entering the box should collide with a potassium atom, the apparatus was kept between 180°C and 205°C. This temperature range corresponds to a range of electronic mean free paths from 6 mm to 2 mm, and of vapor pressures from 0.0018 to 0.005 mm of mercury.

Under our final conditions, the space charge limited current from F was independent of the heating current for temperatures well below the rated limit of the filament. The presence of potassium in the apparatus increased the emission from filament C so much that sufficient electrons to cause measurable ionization were given off at a temperature below visible redness. Thus the velocity range of the emitted electrons due to temperature was small.

Some typical curves are shown in Fig. 3. Only relative values of the ionization potentials, of course, are given accurately by this method, since we had no easy way of correcting for the contact differences of potential involved. We have assumed that the initial rise in the curve corresponds to the ionization potential, which from spectroscopic data is 4.32 volts for potassium. All the curves show a second distinct discontinuity nearly one volt above the point at which ionization begins. The average of the separations between the first and second breaks for twenty-three curves is 0.97 ± 0.05 volts. It is interesting to note that just above the first break the curves merge into the horizontal axis asymptotically, making it difficult to determine the exact point at which ionization begins; whereas the second break is very sharp. The sharpness of the second break indicates that the velocity range of the ionizing electrons was small enough to show the true shape of the ionization curve. Thus we conclude that the rounding off of the first break is a true representation showing a slow increase in the ionization probability in the neighborhood of the ionization potential.⁵

As a check on the apparatus we also attempted to verify Lawrence's results on the ultraionization potentials of mercury vapor, before beginning the work on potassium vapor. We found that the discontinuities in mercury vapor were considerably more difficult to reproduce time after time than the single discontinuity in potassium. However, we obtained the following values for the ultraionization potentials of mercury, which are not wholly in agreement with those found by Lawrence.⁷

Lawrence's values	10.40	10.60		11.29		11.70	12.06
Our values	10.40	10.62	10.88	11.28	11.40	11.77	12.16 12.76

DISCUSSION

We may regard the discontinuity in the ionization curve at 0.97 volts above the first ionization potential as indicating the onset of an additional kind of ionization. This may be considered as a second ionization potential at $4.32 + 0.97 = 5.29$ volts. It is tempting to seek a correlation between the

⁵ Simultaneously with the measurement of the change in the space charge limited current by galvanometer G_1 , the total emission from filament C was measured on galvanometer G_2 . We found that the emission from C did not vary over 10 percent over the range of accelerating potentials used in producing the curves. Furthermore, the emission from C was a smooth, almost linear, function of the accelerating potential. Thus the discontinuity in the ionization curves above the ionization potential cannot be due to any abrupt change in the number of electrons entering the box.

⁷ E. O. Lawrence, Phys. Rev. 28, 947 (1926).

second ionization potential by electron impact and the short wave-length peak in Lawrence's work. We should expect to find the onset of a second type of photoionization at 2334Å, corresponding to 5.29 volts. However, in Lawrence's experiment, the second type of photoionization begins at 2700Å and rises to a maximum at 2340Å. Now the second break in our curves corresponds much more closely to the latter value, although we should have expected correlation with the former.

Until recently it was customary⁸ to associate the presence of the second ionization potential in photoionization in potassium with an effect on the molecule. Such evidence as we have as to the association in potassium vapor indicates that for every molecule, there are perhaps 5,000 atoms. Therefore, in order to account for the results, it has been suggested that, for light, the molecule has a much larger absorption coefficient than the atom. Since the change in slope at the second ionization potential in our ionization by electron impact curves is of the same order as the change in slope at the first, it would also mean a very large effective cross section for the molecule for electron impact as compared with the atom. Since this line of argument seems to lead to a conclusion which is difficult to believe, we are inclined to associate the second discontinuity with the onset of a second type of ionization in the atom, for which we have no theory.

A close correlation between the effects of light and electron impact is not to be expected. We know, for example, that in the excitation of an atom by light, the fit between the wave-length of the exciting light and the energy changes in the atom must be exact. However, in the case of electron impact, the colliding electron need have only *sufficient* energy. Similarly, in the field of ionization, we could hardly expect an exact parallelism between the effect of light and the effect of electron impact.

ABSORPTION AND COLLISION BROADENING OF THE MERCURY RESONANCE LINE

BY M. W. ZEMANSKY*

PALMER PHYSICAL LABORATORY, PRINCETON, N. J.

(Received June 9, 1930)

ABSTRACT

Radiation emitted by a mercury resonance lamp. It is shown how an approximate expression for the frequency distribution of the radiation from a resonance lamp can be arrived at, and that it can be represented approximately by a Gauss error curve with a half-breadth depending upon the geometry of the lamp and upon the vapor density, and in general greater than that of the absorption line.

Absorption coefficient and ratio of emission to absorption line breadth. Assuming that all five components of the mercury resonance line are alike both in emission and in absorption, and that any one component of the emission and of the absorption line is a Gauss error curve of half-breadth $\Delta\nu_E$ and $\Delta\nu_D$ respectively ($\Delta\nu_D$ = Doppler breadth), the absorption of a slab of thickness l is calculated as a function of $\kappa(\nu_0)l$, where $\kappa(\nu_0)$ is the absorption coefficient for the center of any one of the components. From experimental values of the absorption, $\kappa(\nu_0)$ is found to be consistent with the theoretical value $1.41 \times 10^{-13}N$ (where N is the number of Hg atoms per cc) provided $\Delta\nu_E/\Delta\nu_D$ is taken to be 1.21 in these experiments, 1.46 in Orthmann's, 1.50 in Hughes and Thomas', 1.15 in Kunze's, and 1.15 in Kopfermann and Tietze's.

Lorentz collision broadening of the absorption line. A theoretical expression is obtained for the absorption coefficient when collision broadening is superimposed upon Doppler broadening, and is evaluated for different values of the frequency and of $\Delta\nu_C/\Delta\nu_D$ where $\Delta\nu_C$ is the Lorentz collision breadth and $\Delta\nu_D$ is the Doppler breadth. With $\kappa(\nu_0)l$ and $\Delta\nu_E/\Delta\nu_D$ equal to the values found for these experiments, the absorption is calculated as a function of $\Delta\nu_C/\Delta\nu_D$. From experimental values of the absorption of mercury vapor in the presence of H_2 , N_2 , A, CO, NH_3 , He, CH_4 , and C_3H_8 , $\Delta\nu_C$ is found as a function of the pressure of each gas. The curves of $\Delta\nu_C$ against pressure yield the effective broadening radius of each molecule, which is found to be directly proportional to the square root of the molecular diamagnetic susceptibility. On the basis of the Langevin theory this means that the effective broadening area of a molecule varies at the product of the number of outer electrons and the mean square radius of all the electronic orbits. The same result is obtained from the experiments of F üchtbauer, Joos and Dinkelacker.

ABSORPTION COEFFICIENT AND RATIO OF EMISSION TO ABSORPTION LINE BREADTH

THE transmission through mercury vapor of the radiation emitted by a mercury resonance lamp has been measured many times under apparently similar conditions, and yet the results have varied very markedly. The resulting values of absorption coefficient have differed from one another by as much as several hundred percent. In an investigation of the quenching of mercury resonance radiation by foreign gases which has been in progress for

* National Research Fellow.

the last two years it was found necessary to know the absorption coefficient of mercury vapor for mercury resonance radiation very accurately. Consequently, this quantity was studied rather carefully with a view to discover, if possible, the causes for the existing discrepancies. The present paper, it is hoped, will clear up those difficulties which have not already been solved by others, and will give a summary of all the work that has been done since 1925, as well as a new set of measurements of the absorption coefficient.

THE RADIATION EMITTED BY A MERCURY RESONANCE LAMP

It has been shown by Wood¹ that the mercury resonance line ($\lambda = 2537$) emitted by a mercury arc consists of five components of approximately equal intensity, and that all of these components are absorbed approximately equally by a column of mercury vapor. This has been substantiated by very careful measurements of the Zeeman effect of the mercury resonance line in a recent paper by Schein.² The intensity distribution of the radiation emitted by a mercury resonance lamp, however, is not known accurately as a function of the vapor density, the type of resonance lamp, dimensions, etc. It was assumed by Orthmann,³ Kunze,⁴ and Schein that the radiation emitted by a mercury resonance lamp was similar in intensity distribution to radiation whose half-breadth was equal to that of the absorption line but which had been absorbed slightly by passing through a thin layer of mercury vapor on its way out of the resonance lamp. This assumption was used by Orthmann and Kunze to calculate a correction factor which was applied to all the experimental values of the absorption. Schein, however, recognized that this assumption implies that the radiation emitted by a resonance lamp has a half-breadth slightly larger than that of the absorption line, and, by graphical means, estimated that, in his experiments, the ratio was 1.23.

The original supposition, namely, that the radiation emitted by a mercury resonance lamp is similar to that which results when a line of half-breadth equal to that of the absorption line passes through a thin absorbing layer, is only partly true, for when the vapor density in the resonance lamp approaches zero, the intensity should approach zero, whereas, according to the above assumption, it approaches a constant. A more satisfactory picture of the situation can be made on the basis of the following approximations:

1. The original stimulating radiation from the arc has a breadth that is so wide in comparison to the absorption line breadth of the vapor in the resonance lamp that it can be regarded as a continuous spectrum in the limited range of frequencies under consideration. Call this intensity A .
2. The radiation that is re-emitted in the body of the resonance lamp is a fraction ϵ of that amount of A which is absorbed in a column of average thickness l_1 . Call this radiation $A_1(\nu)$.

² M. Schein, *Helv. Phys. Act.* Vol. II, Sup. I (1929).

³ W. Orthmann, *Ann. d. Physik* **78**, 601 (1925).

⁴ P. Kunze, *Ann. d. Physik* **85**, 1013 (1928).

3. The radiation that finally emerges from the resonance lamp is the radiation $A_1(\nu)$ after it has passed through a column of vapor of average thickness l_2 . Call this radiation $A_2(\nu)$.

The situation is represented graphically in Fig. 1.

Fig. 1. Schematic representation of a resonance lamp.

Let us consider only one component of the mercury resonance line, inasmuch as all the components behave the same way. We have

$$A_1(\nu) = \epsilon A (1 - e^{-\kappa(\nu)l_1})$$

$$A_2(\nu) = A_1(\nu) e^{-\kappa(\nu)l_2}$$

where $\kappa(\nu)$ is the absorption coefficient of the vapor in the resonance lamp for the frequency range between ν and $\nu + d\nu$. Let us make the usual assumption:

$$\kappa(\nu) = \kappa(\nu_0) e^{-[2(\nu - \nu_0)/\Delta\nu_A]^2 \log_e 2}$$

where $\kappa(\nu_0)$ is the absorption coefficient for the center of the line of frequency ν_0 , and $\Delta\nu_A$ is the half-breadth of the absorption line. Calling $2(\nu - \nu_0)/\Delta\nu_A (\log_e 2)^{1/2} = \omega$, we have then

$$\kappa(\omega) = \kappa(0) e^{-\omega^2}.$$

Let us further assume that the geometry of the resonance lamp has been so arranged that l_1 is very nearly equal to l_2 . This is not essential, but it simplifies matters somewhat. Then, after substitution, we have

$$A_2(\omega) = \epsilon A (1 - e^{-xe - \omega^2}) e^{-xe - \omega^2} \quad (1)$$

where $x = \kappa(\nu_0)l_1 = \kappa(\nu_0)l_2$.

Plotting this expression for different values of x , it is found that it resembles a Gauss error curve fairly well with a half-breadth greater than that for the curve $e^{-\omega^2}$, that is, greater than the half-breadth of the absorption line. Calling this new half-breadth $\Delta\nu_E$, $\Delta\nu_E/\Delta\nu_A$ was found graphically to be 1.16 when $x = 0.25$ and 1.33 when $x = 0.50$. As the vapor density approaches zero, x approaches zero, and Eq. (1) approaches $x\epsilon A e^{-\omega^2}$, which is correct, because the intensity approaches zero, and the half-breadth approaches the absorption line breadth.

Burger and van Cittert⁵ considered the broadening of a spectral line by absorption and obtained an expression for the breadth as a function of x . Unfortunately, however, their results can not be applied to the case of a resonance lamp.

If there were some way of estimating x for a particular resonance lamp it might be worth while to use the expression given by Eq. (1) in what is to follow. Since, however, there is no way of knowing how accurately x can be estimated, it is better to replace Eq. (1) by a Gauss error curve of half-breadth $\Delta\nu_E$ where $\Delta\nu_E$ is to be determined by experiment.

Two types of resonance lamp have been used to obtain resonance radiation. In the first one, the resonance radiation is taken off the incident window at about 45° to the incident beam,⁶ and in the second, it emerges from a separate window at an angle of 90° to the incident beam.⁷ It is obvious that the second type can be designed to correspond to a much smaller value of x than the first. It is therefore to be expected that the experiments conducted with the 90° type will involve a smaller value of $\Delta\nu_E$ than those performed with one of the 45° type.

THE ABSORPTION OF RADIATION

When radiation of frequency between ν and $\nu + d\nu$ and intensity $K(\nu, 0)$ passes through an absorbing slab of thickness l with absorption coefficient $\kappa(\nu)$, then the transmitted radiation, $K(\nu, l)$ is given by⁸

$$K(\nu, l) = K(\nu, 0)e^{-\kappa(\nu)l}.$$

Let us suppose, as usual, that the emission and absorption lines are Gauss error curves with half-breadths $\Delta\nu_E$ and $\Delta\nu_A$ respectively. Then

$$K(\nu, 0) = K(\nu_0, 0)e^{-[2(\nu - \nu_0)/\Delta\nu_E]^2 \log_e 2}$$

$$\kappa(\nu) = \kappa(\nu_0)e^{-[2(\nu - \nu_0)/\Delta\nu_A]^2 \log_e 2}$$

and the absorption, A , is

$$A = 1 - \frac{\int_{-\infty}^{\infty} e^{-[\omega^2 + \kappa(\nu_0)l]e^{-(\Delta\nu_E/\Delta\nu_A)^2}} d\omega}{\int_{-\infty}^{\infty} e^{-\omega^2} d\omega}$$

where

$$\omega = \frac{2(\nu - \nu_0)}{\Delta\nu_E}(\log_e 2)^{1/2}.$$

For values of $\kappa(\nu_0)l \leq 1.5$, the series expansion of Eq. (2) is satisfactory for numerical computation

⁷ P. Kunze, reference 4.

⁸ A. v. Malinowski, *Ann. d. Physik* **44**, 935 (1914).

$$A = \kappa(\nu_0)l \cdot \frac{1}{\left(1 + \left(\frac{\Delta\nu_E}{\Delta\nu_A}\right)^2\right)^{1/2}} - \frac{[\kappa(\nu_0)l]^2}{2!} \cdot \frac{1}{\left(1 + 2\left(\frac{\Delta\nu_E}{\Delta\nu_A}\right)^2\right)^{1/2}} + \dots$$

$$\dots + (-1)^n \frac{[\kappa(\nu_0)l]^n}{n!} \cdot \frac{1}{\left(1 + n\left(\frac{\Delta\nu_E}{\Delta\nu_A}\right)^2\right)^{1/2}} + \dots$$

$$A = 1 - \frac{\int_{-\infty}^{+\infty} e^{-[\omega^2 + \kappa(\nu_0)l - (\Delta\nu_E/\Delta\nu_A)\omega]^2} d\omega}{\int_{-\infty}^{\infty} e^{-\omega^2} d\omega}.$$

TABLE I. Values of A .

$\frac{\Delta\nu_E}{\Delta\nu_A}$

4.5	.989	.977	.897		.640	.480

For values of $\kappa(\nu_0)l > 1.5$ it was found more convenient to evaluate A graphically. The values of A for different values of $\kappa(\nu_0)l$ and $\Delta\nu_E/\Delta\nu_A$ are given in Table I, and are plotted in Fig. 2. Curves of A against $\kappa(\nu_0)l$ for various values of $\Delta\nu_E/\Delta\nu_A$ are shown in Fig. 3. DeGroot⁹ has given curves of the same character as those of Fig. 2, but in a form that is not very convenient for the purpose at hand.

When $\Delta\nu_E/\Delta\nu_A$ is known, a curve of A against $\kappa(\nu_0)l$ can be drawn, and from experimental values of A and l , $\kappa(\nu_0)$ can be obtained. Values of $\kappa(\nu_0)$ for mercury vapor at a density corresponding to 20° C obtained by different authors under different conditions are given in Table II.

It will be seen from Fig. 3 that, if a curve of A against $\kappa(\nu_0)l$ for $\Delta\nu_E/\Delta\nu_A = a$, where a is any number, be used in a situation which really requires the use of a curve for $\Delta\nu_E/\Delta\nu_A > a$, the resulting values of $\kappa(\nu_0)l$ will be too small. It is to be expected, therefore, that the smallest values of $\kappa(\nu_0)$ will correspond to the largest values of $\Delta\nu_E/\Delta\nu_A$. This is seen to be the case, for it was pointed out in the beginning that the 45° type of resonance lamp yields a broader line than the 90° type.

There is another important error that can result in a final value of $\kappa(\nu_0)$ that is too small, namely, the reception by the photoelectric cell of scattered

⁹ W. de Groot, *Physica* 9, 263 (1929).

Fig. 2. Values of A for different values of $\kappa(\nu_0)l$ and $\Delta\nu_E/\Delta\nu_A$.

TABLE II.

	Type of Resonance Lamp	Method of computing $\kappa(\nu_0)$ from A	at 20°C
Orthmann ³	45°	Used curve of A against $\kappa(\nu_0)l$ for $\Delta\nu_E/\Delta\nu_A=1$ and applied a correction factor to A to take into account absorption in the resonance lamp.	3.1
Hughes and Thomas ⁶	45°	Used exponential law of absorption which is equivalent to assuming $\Delta\nu_E/\Delta\nu_A=0$	1.24
Schein ²	90°	Used curve of A against $\kappa(\nu_0)l$ for $\Delta\nu_E/\Delta\nu_A=1.23$ but computed $\Delta\nu_E/\Delta\nu_A$ inaccurately.	3.77
Kunze ⁴	90°	Same as Orthmann	5.2
Kopfermann and Tietze ¹⁰	90°	Used formula due to Ladenburg for a situation in which the emitting and absorbing slabs are both infinitesimally thin.	5.2
Author	90°	Used curve of A against $\kappa(\nu_0)l$ for $\Delta\nu_E/\Delta\nu_A$ equal to that value which makes $\kappa(\nu_0)l$ vary linearly with Nl . This value was found to be 1.21.	5.61

radiation along with the transmitted radiation. If the photoelectric cell is placed close to the emerging window, and if the diaphragm which limits the incident beam is in front of the incident window, then a portion of the scattered radiation emitted by the *whole* emerging face is received by the photoelectric cell, resulting in a smaller value of A . It has been found by experiment that no scattered radiation reaches the photoelectric cell if the following conditions are adhered to:

1. The diaphragm limits the incident beam to a diameter of about 1 cm, and is placed over the *emerging* window.
2. The photoelectric cell is no nearer than 7 cm from the diaphragm.

It is believed that, in the experiments of Orthmann and in those of Hughes and Thomas, this was a possible source of error when the mercury vapor density was high enough to give rise to appreciable scattering. In all of the previous experiments, it is believed, an incorrect curve of A against $\kappa(\nu_0)l$ was used to compute the absorption coefficient.

APPARATUS

There is nothing essentially new in the apparatus used in these experiments, so that we shall limit ourselves to a very brief description.

Arc. Quartz mercury arc made by Cooper Hewitt, water-cooled and magnetically deflected.

Resonance lamp. 90° type with crystalline quartz windows cemented on with picein wax. Between it and the mercury diffusion pump there was a trap which was kept surrounded by ice. The drop of liquid mercury in a side tube was also kept in an ice bath. The exciting radiation from the arc illu-

¹⁰ H. Kopfermann and W. Tietze, *Zeits. f. Physik* 56, 604 (1929).

minated about 5 mm of the incident window and the resonance radiation was taken off an area of the emerging window about 5 mm in diameter.

Absorption cell. A disk of heavy Pyrex glass about 4.5 cm inside diameter, and 0.792 cm in length was cut as shown in Fig. 4. Two crystalline quartz windows were cut in the same way and cemented on with picein wax. This was then cemented to a Pyrex tube about 10 cm long and 2 cm in diameter in which was placed a drop of mercury. There was thus a large opening between the tube containing the drop of mercury and the absorption cell proper, which enabled equilibrium conditions to be obtained rapidly.

The absorption cell was connected to the pumps through a glass spiral about a foot in diameter, which had sufficient flexibility to allow the cell to be moved in and out of the path of the light beam. A diaphragm with an

Fig. 4. Absorption cell.

aperture of about 1 cm remained fixed in space on the emerging side of the cell.

The photoelectric cell. The cell was made of fused quartz and had a platinum plate. It was first thoroughly cleaned and baked out, and then about 5 cm of H_2 was admitted. A discharge was passed through the H_2 by a small induction coil and then the H_2 was pumped out. This was repeated a few times until the platinum became slightly discolored. About 4 mm of H_2 was then introduced and the cell was sealed off. It was run on about 200 volts and a sensitive Compton electrometer was used to measure the current. The linearity of the cell at various voltages was tested with calibrated screens.

METHOD

With liquid air on the absorption cell the transmission of the quartz windows was measured and compared with the transmission of a piece of

cellophane which was mounted beside the cell and which came in front of the diaphragm when the cell was moved aside. The cellophane was used to cut down the intensity of the incident light by a known amount when it was measured. The mercury vapor in the absorption cell was maintained at constant density by a suitable substance contained in a Dewar flask which moved with the cell. Melting Benzol was used for the temperature 4.2°C and melting paraxylene for 12.1°C . Water was used for temperatures between 15 and 20°C . The absorption cell proper was always at room temperature which was held as near 20°C as possible. In calculating the number of mer-

cury atoms per cc the vapor pressure was obtained from the International Critical Tables and the Knudsen correction was applied. In determining the transmission at a particular temperature, readings were taken through the cell and then through the cellophane at least six times.

Liquid air was put on the resonance lamp and the sensitivity of the photoelectric cell was increased by increasing the voltage. The absorption of the radiation emitted by the resonance lamp was then measured and found to be less than the radiation emitted by the lamp at 0°C . This was due to diffuse reflection in the resonance lamp of the edges of the broad 2537 line

from the arc. Other wave-lengths did not affect the photoelectric plate, for the reason that platinum treated with hydrogen has a long wave-length limit only a little above 2537. It was estimated that about 1 percent of the radiation from the resonance lamp at 0°C consisted of unabsorbable radiation. Every reading was therefore corrected to take account of this.

The results, along with those of others, are shown in Table III, and plotted in Fig. 5.

Fig. 5. A as a function of Nl .

It will be seen in Fig. 5 that all the measurements fall into two groups. those taken with the 90° type of resonance lamp, and those taken with the 45° type, the former yielding much larger values of the absorption. Both groups, however must correspond to the same values of $\kappa(\nu_0)l$. Inasmuch as it is impossible to calculate accurately $\Delta\nu_E/\Delta\nu_A$, the particular curve of A against $\kappa(\nu_0)l$ for each group is not immediately at hand. It must be chosen by appeal to theory as follows:

It is a well-known result that:¹¹

$$\int_0^\infty (\kappa\nu) d\nu = \frac{h\nu_0 N}{4\pi} B_{1 \rightarrow 2}$$

where N = no. of absorbing atoms per cc

ν_0 = frequency of center of line

$B_{1 \rightarrow 2}$ = Einstein coefficient defined in terms of light intensity, and where the integration is to be taken over all the fine structure components of the absorption line. Using the Einstein relations

¹¹ E. A. Milne, M.N. of R.A.S. **85**, 111 (1924).

$$\frac{A_{2 \rightarrow 1}}{B_{1 \rightarrow 2}} = \frac{2h\nu^3}{c^2} \cdot \frac{q_1}{q_2}$$

and $A_{2 \rightarrow 1} = 1/\tau$, we have

$$\int_0^\infty \kappa(\nu) d\nu = \frac{\lambda_0^2}{8\pi\tau} \cdot \frac{q_2}{q_1} \cdot N$$

and substituting $\lambda_0 = 2.537 \times 10^{-5}$ cm, $\tau = 10^{-7}$ sec.¹² and $q_2/q_1 = 3$, we get

$$\int_0^\infty \kappa(\nu) d\nu = 7.68 \times 10^{-4} N.$$

Since each component of the absorption line obeys

$$\kappa(\nu) = \kappa(\nu_0) e^{-[2(\nu - \nu_0)/\Delta\nu_A]^2 \log_e 2}$$

and since there are five components,

$$\begin{aligned} \int_0^\infty \kappa(\nu) d\nu &= 5 \left(\frac{\pi}{4 \log_e 2} \right)^{1/2} \kappa(\nu_0) \Delta\nu_A \\ &= 5 \times 1.07 \kappa(\nu_0) \Delta\nu_A \end{aligned}$$

whence finally

$$\kappa(\nu_0) l = \frac{1.44 \times 10^{-4}}{\Delta\nu_A} \cdot Nl. \quad (3)$$

In none of the experiments did the mercury vapor pressure ever become high enough to involve Lorentz collision broadening or Holtzmark coupling broadening of the absorption line. $\Delta\nu_A$ therefore, is the Doppler breadth $\Delta\nu_D$, and since the temperature of the absorption cell proper was always at 20°C, $\Delta\nu_D$ is constant. The Doppler breadth of a line is known to be $7.16 \times 10^{-7} \nu_0 (T/M)^{1/2}$ sec⁻¹ where T is the absolute temperature and M is the molecular weight. For mercury at 20°C, $\Delta\nu_D = 1.02 \times 10^9$ sec⁻¹, and consequently Eq. (3) becomes

$$\kappa(\nu_0) l = 1.41 \times 10^{-13} Nl. \quad (4)$$

In Fig. 6, Eq. (4) is shown as a heavy line. The individual points were obtained as follows:

A curve between $\kappa(\nu_0)l$ and A was sought which, in conjunction with the author's values of A , would give values of $\kappa(\nu_0)l$ that varied linearly with Nl . It was found that the curve corresponding to $\Delta\nu_E/\Delta\nu_A$ equal to 1.21 achieved this, and at the same time, agreed well with Eq. (4). Curves of $\kappa(\nu_0)l$ and A were then sought which, in conjunction with the other experimental values of A , would give values of $\kappa(\nu_0)l$ that agreed best with Eq. (4). In this way the curves corresponding to the values of $\Delta\nu_E/\Delta\nu_A$ given in Table III,

column (6) were obtained, and the values of $\kappa(\nu_0)l$ in column (7) were obtained from these curves and experimental values of A . The values of $\kappa(\nu_0)l$ in column (8) were computed from Eq. (4). The agreement with theory is shown in Fig. 6.

Fig. 6. $\kappa(\nu_0)l$ as a function of Nl .

LORENTZ COLLISION BROADENING

When an absorption line is broadened by Doppler broadening only, the absorption coefficient is given by

$$\kappa(\nu) = \kappa(\nu_0) e^{-[2(\nu - \nu_0)/\Delta\nu_D]^2 \log_e 2}$$

where $\Delta\nu_D$ = Doppler breadth. Under the influence of collision broadening, the absorption coefficient varies with the frequency according to a curve of the type

$$\frac{1}{1 + \left[\frac{2(\nu - \nu_0)}{\Delta\nu_C} \right]^2}$$

where $\Delta\nu_C$ = collision breadth = no. of impacts per sec./ π . With collision broadening superimposed on Doppler broadening

$$\kappa(\nu) = \frac{2\kappa(\nu_0)}{\pi\Delta\nu_C} \int_{-\infty}^{\infty} \frac{e^{-(2\delta/\Delta\nu_D)^2 \log_e 2}}{1 + \left[\frac{2}{\Delta\nu_C} (\nu - \nu_0 - \delta) \right]^2} d\delta$$

$$= \frac{2\kappa(\nu_0)}{\pi\Delta\nu_C} \int_{-\infty}^{\infty} \frac{e^{-[2/\Delta\nu_D(\nu-\nu_0-\delta)]^2 \log_e 2}}{1 + \left(\frac{2}{\Delta\nu_C}\delta\right)^2} d\delta$$

where $\kappa(\nu_0)$ = abs. coeff. of center of line when Doppler broadening only is effective, i.e., for zero pressure of foreign gas. Call

$$\frac{2(\nu - \nu_0)}{\Delta\nu_D} (\log_e 2)^{1/2} = q \quad \text{and} \quad \frac{\Delta\nu_C}{\Delta\nu_D} (\log_e 2)^{1/2} = p$$

and let

$$x = \frac{2\delta}{\Delta\nu_D} (\log_e 2)^{1/2}.$$

Then

$$\begin{aligned} \frac{\kappa(\nu)}{\kappa(\nu_0)} &= \frac{p}{\pi} \int_{-\infty}^{\infty} \frac{e^{-(q-x)^2}}{p^2 + x^2} dx \\ &= \frac{2p}{\pi} e^{-q^2} \int_0^{\infty} \frac{e^{-x^2} \cos 2iqx}{p^2 + x^2} dx. \end{aligned}$$

Now

$$\frac{1}{p^2 + x^2} = \int_0^{\infty} e^{-(p^2 + x^2)u} du$$

whence

$$\begin{aligned} \frac{\kappa(\nu)}{\kappa(\nu_0)} &= \frac{2p}{\pi} e^{-q^2} \int_0^{\infty} e^{-p^2 u} du \int_0^{\infty} e^{-(1+u)x^2} \cos 2iqx dx \\ &= \frac{2p}{\pi} e^{-q^2} \int_0^{\infty} e^{-p^2 u} du \frac{1}{2} \left(\frac{\pi}{1+u} \right)^{1/2} e^{q^2/(1+u)}. \end{aligned}$$

Let $1+u = t^2/p^2$, and we have, finally

$$\frac{\kappa(\nu)}{\kappa(\nu_0)} = \frac{2}{(\pi)^{1/2}} e^{p^2 - q^2} \int_p^{\infty} e^{-t^2 + (p^2 q^2 / t^2)} dt. \quad (5)$$

When there is no collision broadening, $p = 0$, and

$$\kappa(\nu) = \kappa(\nu_0) e^{-q^2} \frac{2}{(\pi)^{1/2}} \int_0^{\infty} e^{-t^2} dt = \kappa(\nu_0) e^{-q^2}.$$

At extremely high foreign gas pressures p is very large, and the original expression for $\kappa(\nu)/\kappa(\nu_0)$ can be shown to reduce to $1/(\pi)^{1/2} \cdot p/p^2 + q^2$. It can readily be verified that, for all values of p ,

$$\int_0^{\infty} \kappa(\nu) d\nu = \left(\frac{\pi}{4 \log_e 2} \right)^{1/2} \kappa(\nu_0) \Delta\nu_D$$

which is required by the constancy of the Einstein B coefficient.

In order to evaluate the integral in Eq. (5), we proceed as follows:¹³

Expanding $e^{p^2 q^2 / t^2}$ we have

$$\frac{\kappa(\nu)}{\kappa(\nu_0)} = \sum_{n=0}^{\infty} I_n(p) \frac{e^{-q^2} q^{2n}}{n!}$$

where

$$I_n(p) = \frac{2}{(\pi)^{1/2}} e^{p^2} p^{2n} \int_p^{\infty} e^{-t^2} \frac{dt}{t^{2n}}.$$

Integrating by parts (starting with (dt/t^{2n})) we obtain a convenient means for computing successively all the $I_n(p)$,

$$I_n(p) = \frac{p}{2n-1} \left(\frac{2}{\pi^{1/2}} - 2p I_{n-1}(p) \right)$$

and

$$I_0(p) = e^{p^2} \frac{2}{(\pi)^{1/2}} \int_p^{\infty} e^{-t^2} dt$$

which can be obtained from tables.

$\kappa(\nu)/\kappa(\nu_0)$ was evaluated for different values of p and q and the results are given in Table IV.

$$\frac{\kappa(\nu)}{\kappa(\nu_0)} = \frac{2}{\pi^{1/2}} e^{p^2 - q^2} \int_p^{\infty} e^{-t^2 + (p^2 q^2 / t^2)} dt$$

$$p = (\log_e 2)^{1/2} \frac{\Delta\nu_C}{\Delta\nu_D}, \quad q = (\log_e 2)^{1/2} \frac{2(\nu - \nu_0)}{\Delta\nu_D}$$

TABLE IV. Values of $\kappa(\nu)/\kappa(\nu_0)$.

The absorption is given, as before, by

$$A = 1 - \frac{K(\nu_0, 0) \int_0^{\infty} e^{-[2(\nu - \nu_0) / \Delta\nu_E]^2 \log_e 2} \cdot e^{-\kappa(\nu) l} d\nu}{K(\nu_0, 0) \int_0^{\infty} e^{-[2(\nu - \nu_0) / \Delta\nu_E]^2 \log_e 2} d\nu}$$

¹³ I am indebted to Dr. T. H. Gronwall for the method of evaluating Eq. (5), and to Professor H. P. Robertson for valuable help throughout the calculation.

which becomes

$$A = 1 - \frac{\int_{-\infty}^{\infty} e^{-[(q/\Delta\nu_E/\Delta\nu_D)^2 + \kappa(\nu)/\kappa(\nu_0) \cdot \kappa(\nu_0)l]} dq}{\int_{-\infty}^{\infty} e^{-(q/\Delta\nu_E/\Delta\nu_D)^2} dq}$$

and which can be evaluated graphically for any situation in which $\kappa(\nu_0)l$ and $\Delta\nu_E/\Delta\nu_D$ are known. This was done for these experiments at 20 °C for which $\kappa(\nu_0)l = 4.44$ and $\Delta\nu_E/\Delta\nu_D = 1.21$, and for Orthmann's experiments at 15.5°C for which $\kappa(\nu_0)l = 3.22$ and $\Delta\nu_E/\Delta\nu_D = 1.46$. The results are given in Table V and Fig. 7.

$$A = 1 - \frac{\int_{-\infty}^{\infty} e^{-[(q/\Delta\nu_E/\Delta\nu_D)^2 + \kappa(\nu)/\kappa(\nu_0) \cdot \kappa(\nu_0)l]} dq}{\int_{-\infty}^{\infty} e^{-(q/\Delta\nu_E/\Delta\nu_D)^2} dq}$$

$$\frac{\kappa(\nu)}{\kappa(\nu_0)} = \frac{2}{\pi^{1/2}} e^{p^2 - q^2} \int_p^{\infty} e^{-t^2 + (p^2 q^2 / t^2)} dt.$$

From the curves in Fig. 7 it is possible to obtain the collision breadth of the mercury absorption line merely by measuring the absorption. The advantage of this is that low enough foreign gas pressures may be used so that the five fine structure components of the mercury resonance line will not merge into one another, as was the case in the experiments of Füchtbauer Joos and Dinkelacker¹⁴ who broadened the line by foreign gases at pressures up to fifty atmospheres. There is one disadvantage, however, in that the asymmetry in the line broadening predicted by theory and observed by Minkowski¹⁵ in the case of sodium cannot be taken into account. It will be seen later how this affects the final results. Nevertheless it is believed that this method of measuring the magnitude of the collision breadth

¹⁴ C. Füchtbauer, G. Joos, and O. Dinkelacker, *Ann. d. Physik* **71**, 204 (1923).

¹⁵ R. Minkowski, *Zeits. f. Physik* **55**, 16 (1929).

of a line is superior to the photographic method, because it enables one to separate the collision breadth from the Doppler breadth easily. A spectrogram of an absorption line which has been broadened only slightly by a foreign gas could be used to obtain the collision breadth provided one plotted

Fig. 7. A as a function of $\Delta\nu_E/\Delta\nu_D$. Curve I, $\kappa(\nu_0)l=4.44$, $\Delta\nu_E/\Delta\nu_D=1.21$. Curve II, $\kappa(\nu_0)l=3.22$, $\Delta\nu_E/\Delta\nu_D=1.46$.

measured values of $\kappa(\nu)/\kappa(\nu_0)$ against frequency, and compared these curves with those obtained from Eq. (5). A correction would have to be made, of course, for the frequency shift due to asymmetrical broadening. It is doubtful whether existing experimental data on absorption lines are sufficiently ac-

Fig. 8a and b. $\Delta\nu_C/\Delta\nu_D$ as a function of pressure.

curate for this purpose. The spectrograms of the 2537 absorption line obtained by Füchtbauer, Joos and Dinkelacker at very high foreign gas pressures yield values of the collision breadth that are somewhat in doubt be-

cause of the fact that the fine structure of the line has been completely wiped out. Nevertheless the values obtained by them are very interesting and will be referred to later.

A number of foreign gases were used to broaden the line, and the results are given in Table VI and in Fig. 8. It is seen in Fig. 8 that the collision breadth plotted against the pressure of the foreign gas does not yield a straight line passing through the origin, as it should according to the relation:

$$\Delta\nu_C = \frac{\text{no. of impacts per sec.}}{\pi}$$

It is believed that this is due to the failure to take into account the asymmetry in line broadening, but that the error will not be large if the linear portions of the curves are considered. The three points for H_2 shown in Fig. 8 obtained by Orthmann five years ago under entirely different conditions as to mercury vapor density, thickness of cell, type of resonance lamp, etc., agree well enough to constitute an excellent check on the method as a whole.

Calling Z the number of impacts per mercury atom per sec, we have from kinetic theory

$$Z = 2\sigma_E^2 \frac{9.71 \times 10^{18} p'}{T} \left(2\pi kT \left(\frac{1}{m} + \frac{1}{M} \right) \right)^{1/2}$$

where T is the absolute temperature, p' the pressure in mm, k Boltzmann's constant, m the mass of a mercury atom, M the mass of a foreign gas molecule, and σ_E the effective distance between centers.

Since $\Delta\nu_C = Z/\pi$,

$$\frac{Z}{p'} = \pi \Delta\nu_D \frac{\Delta\nu_C/\Delta\nu_D}{p'} = \pi \times 1.02 \times 10^9 \times \text{slope of line in Fig. 8} \quad (6)$$

and

$$\frac{Z}{\sigma_E^2 p'} = \frac{2 \times 9.71 \times 10^{18}}{T} \left(2\pi kT \left(\frac{1}{m} + \frac{1}{M} \right) \right)^{1/2} \quad (7)$$

from which σ_E^2 can be calculated.¹⁵ The values of Z/p' , $Z\sigma_E^2 p'$, and σ_E^2 obtained from these experiments along with those from the work of Fuchtbauer, Joos, and Dinkelacker are given in Table VII.

DISCUSSION

It is seen from Table VII that all the values of σ_E^2 are larger than the normal ones, which vary from about 9 to 12×10^{-16} cm, in agreement with the ideas of Kallmann and London.¹⁷ The most striking result, however, is obtained if we adopt the point of view that, in the collision process, the mercury atom has a constant radius equal to the gas-kinetic radius (1.80×10^{-8} cm) and that each broadening gas has its own effective radius. The effective radius of each gas is then obtained by subtracting 1.80×10^{-8} from σ_E . Values of $\sigma_E - 1.80 \times 10^{-8}$ are given in Table VII along with values of

¹⁵ The values of σ_E^2 obtained from these experiments are to be regarded as lower limits because of the error in neglecting asymmetry. Relative values, however, are probably quite reliable.

¹⁷ Kallmann and London, Zeits. f. Phys. Chem. Abt. B, 2 (1929).

the molecular diamagnetic susceptibility, χ_M . All the values of χ_M are experimental ones¹⁸ except that for CO which was obtained by adding the susceptibilities of C and O. The justification for this is that it yields a result almost equal to that of N_2 which is known to be similar to CO in most of its properties.

In Fig. 9 the effective radius is plotted against the square root of the susceptibility, and very good straight lines are obtained for both Fuchtbauer's and these results. The agreement between the two lines is no less remarkable than the lines themselves, inasmuch as the two methods are so radically different. It is possible that the correct line lies between the two

Fig. 9. σ_E as a function of $(-\chi_M)^{1/2}$.

because of the error that is peculiar to each method. The Langevin theory of diamagnetism allows us to give a meaning to this linear relation. According to the simple theory of diamagnetism for an atom, the atomic susceptibility is given by $-(e^2/6mc^2) n \bar{r}^2$ where n is the number of outer electrons of the atom, and \bar{r}^2 is the mean square radius of all the electronic orbits. Applying this relation to all the molecules in question, we get the result that the effective cross-section of a molecule for collision broadening is proportional to the number of outer electrons and to the mean square radius of the electronic orbits, a result that is quite interesting.

¹⁸ A. P. Wills and G. Hector, Phys. Rev. 23, 209 (1924), G. Hector, Phys. Rev. 24, 418 (1924), F. Bitter, Phys. Rev. 33, 389 (1929), Stoner "Magnetism and Atomic Structure."

According to this result, oxygen, although it is strongly paramagnetic, and cannot be plotted in Fig. 9, ought to behave like N_2 or CO, because O_2 has 16 electrons and a gas-kinetic radius of 1.47×10^{-8} cm, whereas N_2 and CO have each 14 electrons and radii equal to 1.58×10^{-8} cm and 1.60×10^{-8} cm respectively. The effective broadening radius of O_2 , according to Füchtbauer's results is 6.27×10^{-8} cm in good agreement with Füchtbauer's value for N_2 , 6.25×10^{-8} cm. The author did not use O_2 as a broadening agent for fear that at such high O_2 pressures, the inside walls of the absorption cell would become covered with HgO , which would lower their transmission and completely obscure any slight change in the absorption of the mercury vapor.

The only points that lie seriously off their respective straight lines in Fig. 9 are Füchtbauer's point for CO_2 and the author's for C_3H_8 . There is a possibility that the value for the diamagnetic susceptibility of CO_2 , -18.7×10^{-6} is too small. It was measured by Soné, whose value for N_2 is considerably smaller than the accepted value. It is not likely, however, that the value for the susceptibility of C_3H_8 , measured by Bitter, is too large, because it was based on Hector and Wills' values for N_2 and H_2 , and also because it fits in well with the higher hydrocarbons. Its departure from the line in Fig. 9 is much too great to be accounted for on the basis of experimental error. There is a possibility that, in the time that elapsed between its preparation and its use, it became contaminated. Unfortunately there was not sufficient time at the author's disposal to settle the question definitely. It would be very interesting to measure the effective broadening radius of all the gaseous hydrocarbons, as well as other organic gases, and it is quite likely that this will be done next year.

In conclusion, the author would like to express his indebtedness to Mr. L. J. Buttolph of the General Electric Vapor Lamp Co. for the loan of a mercury arc, and to Dr. J. R. Bates for his kindness in supplying methane and propane. It is a pleasure also to acknowledge my debt to the National Research Council for the opportunity of engaging in this research and to Professor K. T. Compton for the privilege of working in Palmer Physical Laboratory.

THE EFFECT OF SMALL ANGLE SCATTERING ON THE ELECTRON ABSORPTION COEFFICIENT

BY METTA CLARE GREEN

DEPARTMENT OF PHYSICS, UNIVERSITY OF CALIFORNIA

(Received June 7, 1930)

ABSTRACT

An indirect study of the scattering of electrons by gas molecules has been made by measuring electron absorption coefficients in an apparatus containing a Faraday cylinder of variable aperture. A straight path method was used in which electrons from an oxide-coated filament were given a desired velocity and made to traverse a 7.5 cm path to the collector. A retarding potential between the cylinder and its shield kept out all electrons which had suffered inelastic collisions as well as those which had been scattered outside of the collector opening. Measurements were made in argon, helium, hydrogen, and mercury vapor at accelerating potentials ranging from 11 to 196 volts. The radius of the cylinder aperture varied from one one-hundredth to one tenth of the path length. No consistent variation of the absorption coefficient with opening was found in any case. Theoretical calculations based on scattering laws obtained from inverse square or fifth power laws of force predicted relatively large variations. Calculations made assuming uniform scattering or the Sommerfeld law indicated small changes of the same order of magnitude as the deviations between individual values obtained in this experiment.

INVESTIGATIONS have recently been made by Dymond¹ and Watson,² Harnwell,³ and Arnot⁴ of the distribution of electrons scattered by gas molecules. The experimental curves showing the relation between the intensity of the scattered current per unit solid angle and the scattering angle all indicate relatively large scattering at small angles for both elastic and inelastic collisions. The initial steepness of the slopes of the curves increases with increasing initial electron velocity. Dymond and Watson's curve for elastic scattering of 210 volt electrons in helium gives very rough agreement with Born's⁵ theoretical curve calculated for slower electrons in hydrogen, but, as they point out, this fact is not very significant. Harnwell's original curves for elastic scattering in molecular and monatomic hydrogen compared total scattering between θ and $\theta + d\theta$ with scattering per unit solid angle given by the theoretical equation of Born. When corrected for this error,⁶ his experimental values of scattered intensity per unit solid angle are no longer in agreement with the theoretical values. Arnot found that the curve for elastic scattering of 82 volt electrons in mercury vapor had a steeper initial slope than that of Dymond and Watson's helium curve for electrons of the same

initial velocity. The experimental curves all indicate much less rapid change of scattered intensity with scattering angle at small angles than that given by the theoretical scattering law obtained from an inverse square law of force between the electron and the scattering particle.

Indirect evidence on the angular distribution of electrons scattered by molecules is given by measurements of electron absorption coefficients in gases and vapors. An electron beam is diminished in intensity by collision with molecules of a gas through which it passes, according to the equation, $I = I_0 e^{-\alpha p x}$, where I is the electron current reaching the end of the path, I_0 is the initial current, x , the path length, and α , the absorption coefficient.

Determinations of α all involve measuring the variation of the logarithm of the ratio of the final to the initial current with path length or gas pressure. The rate of variation of α with the diameter of the aperture of the Faraday cylinder used for collecting the final beam should depend on the angular distribution of the scattered electrons. Comparison of data so far collected with different experimental arrangements of apparatus indicates that α is practically constant for relatively large ranges of cylinder aperture. Brode⁷

Fig. 1. Diagram of apparatus.

obtained very good agreement between values of α for cadmium vapor taken in very different types of apparatus. However, quantitative information cannot be obtained by direct comparison of other existing data.

Accordingly a direct experimental study of this question has been made in an apparatus in which a beam of electrons from a hot oxide-coated filament was given a definite velocity and then made to travel a straight path through gas at known pressure to a collector of variable opening.

The experimental arrangement is shown in Fig. 1. F is a small oxide-coated nickel cylinder which is welded to a tungsten wire and is a practically equipotential source of electrons.⁸ S_1 , S_2 and S_3 are circular holes of 5, 2, and 3 mm diameter respectively. C is a Faraday cylinder 9 cm long and 2 cm in diameter, whose shield has a magnetically-operated shutter-opening, O , similar to that of a camera. The diameter of O varied from 2.3 to 17 mm. The distance from S_2 to O is 7.7 cm. Accelerating and retarding potentials, V_1 and V_2 , were applied between the filament and second nickel plate and the Faraday cylinder and its shield, respectively. Galvanometers G and M measured the final electron current and the total emission through S_2 . The

metal parts were all made of nickel and the inside of the tube enclosing the whole apparatus was sputtered with nickel and grounded through M . The earth's magnetic field was neutralized by large Helmholtz coils.

Absorption coefficients were measured in argon, helium, molecular hydrogen and mercury vapor. Electron velocities corresponding to 13, 27.5, and 97 volts accelerating potential were used in argon, helium and hydrogen; in argon 47 and 196 volt electrons were also studied. 40 volt electrons were used in mercury.

Fig. 2. Logarithm of ratio of current, G , at end of path to total current, M , as a function of pressure and aperture radius, A , for 97 volt electrons in argon.

The argon was purified in a calcium arc and the helium and hydrogen were passed through charcoal cooled in liquid air.

With constant accelerating potential, readings of G and M were made for from three to five different pressures for each cylinder aperture. From four to seven different apertures were used for each accelerating potential. The total electron current varied from 2 to 8×10^{-7} amperes, while the currents to the Faraday cylinder were from 2 to 100×10^{-9} amperes. Curves were obtained showing the variation of the final current with the total emission through S_2 for fixed values of pressure, aperture, and accelerating potential.

Readings were always taken in the region where the two currents were proportional to each other.

The true value of the electron velocity was determined by retarding potential curves. Each current, G , was taken as the difference between galvanometer scale deflections for a retarding potential about ten percent less than and one equal to the accelerating potential. The apparent size of the beam was determined by plotting values of G/M against aperture. The opening for which the G/M ratio fell to half its limiting value for wide openings was used to measure the beam radius. Under the conditions of this experiment this was approximately 3 mm.

TABLE I.

Aperture radius		Absorption coefficient, α				Mercury
		Argon				
(mm)	13v	27.5v	47.5v	96.5v	196v	37.5v.
1.1	64.8	43.2	34.4	30.4	18.3	94.5

2.9	70.9	43.9	35.8	30.6	19.9	82.4
3.7		43.2	35.2	31.0	19.8	84.5
4.5	68.6	43.5	35.8	31.4	22.0	89.0
5.3	67.4	42.9	33.8	30.7	21.7	
6.2						94.5
8.5	67.4	44.3	34.0	27.6	20.6	
Av. α	67.8	43.5	35.2	30.3	20.4	91.1

Aperture radius		Absorption coefficient, α				
		Helium		Hydrogen		
(mm)	13v	27.5v	97v	11.5v	27.5v	97v
1.1	14.9	10.8	3.21	27.0	15.1	11.2
2.9	15.2	10.8	3.54	27.0	16.5	10.5
3.7		9.6	4.05			
4.5	13.5	10.1	4.05	27.7	16.2	11.1
6.2			3.88	24.6	15.5	10.8
8.5	14.5	8.3	4.55	25.3	16.0	9.1
Av. α	14.5	9.9	4.12	26.3	15.9	10.5

The gas pressures varied from 2 to 12×10^{-3} mm for argon and helium, from 10 to 50×10^{-3} mm for hydrogen, and from 5 to 25×10^{-4} mm for mercury.

The value of the absorption coefficient was determined in each case by plotting the values of the logarithm of G/M (assumed to be proportional to $\log I/I_0$) against the gas pressure and dividing the slope of the straight line so obtained by the path length. The latter was not clearly defined in the apparatus, but it was assumed to be 7.5 cm. Correction was made for room temperature so that the values of α are in cm^2/cm^3 of gas at 1 mm pressure and 0°C . In Fig. 2 are shown the observed values of the $\log G/M$ plotted as a function of the pressure in argon at 97 volts: it appears that the relationship is linear.

Table I summarizes the experimental results for the variation of the electron absorption coefficients with aperture diameter. Figs. 3 and 4 represent these results graphically for some of the accelerating potentials in argon and hydrogen.

These values of α have a consistent tendency, except in the case of the low velocity measurements in hydrogen, to be higher than those recently obtained by Normand⁹ in this laboratory with a magnetic deflection method.

Fig. 3. Electron absorption coefficient α , as a function of aperture radius and accelerating potential in argon.

In helium this might be partly due to impurities, but it can hardly be ascribed to contamination in the case of argon, since most of the probable impurities would have lower values of α than argon. The difference has not been explained, but it is of interest to note that Jones¹⁰ got consistently higher values of α in mercury with a straight path method than with the magnetic deflection method.

As seen from the table of results, there is no consistent tendency for α to vary with aperture within the limits of error of these measurements.

THEORETICAL DISCUSSION

Assuming an inverse square law of force between the electron and the scattering center one obtains with classical mechanics an expression for the

Fig. 4. Absorption coefficient for 27.5 volt electrons in hydrogen. Circles indicate observed values.

variation of intensity of elastically scattered electrons with scattering angle which is identical in form with that of Rutherford for the scattering of alpha-particles by heavy nuclei:

$$\frac{1}{n} \frac{dN}{dA} = \left(\frac{e^2 Z}{4Er} \right)^2 \frac{1}{\sin^4 \theta/2}$$

where θ is the angle between the original direction of the beam and the radius vector from the scattering center to the scattered particle, n is the intensity per unit area of the incident beam, dN/dA , the number of electrons which have been deflected through an angle θ and fall on unit area at a distance r from the scattering center, e , the electronic charge, E , the initial kinetic energy of the scattered particle, and Z , the atomic number of the scatterer.

Taking into consideration the polarization of the scattering particle by the passing electron Zwicky¹¹ obtained an inverse fifth power law of attraction which would give the scattering formula:

$$\frac{1}{n} \frac{dN}{dA} = \frac{K}{r^2} \frac{1}{(\cos^3 \theta/2 \sin^5 \theta/2)^{1/2}}$$

This is an approximate expression which is valid only for small angle scattering. K is a constant and the other symbols have the above meanings.

The scattering law derived by Sommerfeld¹² on the basis of the wave mechanics considers the interaction of the electron with the "electron cloud"

¹¹ F. Zwicky, Phys. Zeits. **24**, 171 (1923).

¹² A. Sommerfeld, Atombau und Spectrallinien, Wellenmechanischer Ergänzungsband, p. 231.

surrounding the nucleus of the scattering atom. The "electron cloud" is formed by the electrons outside the nucleus, all of which are assumed to be in the K -shell. The derivation neglects any disturbance of the electronic charge distribution of the atom by the field of the passing electron. The equation thus derived is:

$$\left| \frac{\psi_1}{\psi_0} \right|^2 = \left(\frac{e^2 Z}{4Er} \right)^2 \times \frac{1}{(\sin^2 \theta/2 + \alpha^2)^2}$$

In this formula, $|\psi_1/\psi_0|^2$ is the ratio of the intensity of the scattered to the initial beam per unit area and $\alpha = \lambda Z/2\pi a$ where λ is the wave-length of the electron in terms of Planck's constant, h , and its momentum, mv , and a is the radius of the first Bohr orbit of the atom. If α is very small, that is, for very fast electrons, this becomes the Rutherford formula. For slow electrons, of long wave-length, $\sin^2 \theta/2$ becomes negligible in comparison with α^2 and the formula becomes, merely:

$$\left| \frac{\psi_1}{\psi_0} \right|^2 = \left(\frac{e^2 Z}{4Er} \right)^2 \frac{1}{\alpha^4} = \left(\frac{h^2}{4\pi^2 m e^2 Z} \right)^2 \frac{1}{r^2}$$

This indicates uniform scattering in all directions. The above considerations would predict that the intensity of scattering per unit angle would show less variation with angle for slow electrons than that given by the Rutherford formula, but would approach it at higher velocities. That this has been found experimentally has been previously mentioned.

The scattering laws can be applied to determine the theoretical variation of the absorption coefficient with collector aperture by a double integration which takes into account all electrons scattered outside the aperture from every point in the path of the beam.

In the case of the scattering resulting from an inverse square law of force, if $\theta = \tan^{-1} a/(L-x)$ is the angle subtended by the aperture radius at the point of collision, the current scattered beyond the opening per unit intensity of the incident beam per scattering center is given by the expression:

$$\frac{dI}{I} = -K \int_{\tan^{-1} a/(L-x)}^{\pi} \frac{\sin \theta d\theta}{\sin^4 \theta/2} = -2K \left(\frac{(a^2 + (L-x)^2)^{1/2} + (L-x)^2}{a} \right)^2$$

a is the radius of the aperture, x , the distance from the beginning of the path to the point of collision, L , the path length, and $k = 2\pi(e^2 Z/4E)^2$. The same meanings will be attached to these symbols whenever they occur in the following discussion.

Multiplying by $N dx$ to get the effect of all the scattering particles, N being the number of molecules per cc, and integrating from $x=0$ to $x=L$, this equation becomes

$$\log \frac{I}{I_0} = -2KN \left(L + \frac{2}{3} \frac{L^3}{a^2} - \frac{2}{3} a^3 \pm \frac{2}{3} \frac{(a^2 + L^2)^{3/2}}{a^2} \right)$$

I_0 is the current when $x=0$. When a is very small in comparison with L , this may be simplified to:

$$\log \frac{I}{I_0} = -2KN \frac{4}{3} \frac{L^3}{a^2}$$

Since

$$\log \frac{I}{I_0} = -\alpha L p$$

$$\alpha = \frac{8KN}{3p} \frac{L^2}{a^2}.$$

That is, α should vary inversely as the square of the aperture radius. This theoretical variation of α is plotted for 27.5 volt electrons in hydrogen in the lower curve of Fig. 4. The constant K has been chosen arbitrarily to give the theoretical curve the experimental value at the point $a=3$ mm, this being the point at which the size of the collector opening equals that of the beam.

The above derivation, as well as those that follow, is approximate in that it considers only the scattering due to elastic collisions. At 27.5 volts in hydrogen, however, the fraction of inelastic scattering at small angles is small, as indicated by the work of Dymond and Watson and that of Harnwell on velocity and angular distribution of the two types of scattering. Further, this treatment neglects scattering due to collisions after the first and takes no account of space charge in the beam, nor of finite width of the beam. The effect of the size of the electron beam has been recently calculated by Beeck¹³ for the case of uniform scattering. Similar calculations for the scattering resulting from an inverse square law of force show that the effect of the size of the beam is to make the theoretical variation of α with aperture greater and thus to increase the discrepancy between the theoretical and the experimental curves.

The effect of aperture on α can be obtained for an inverse power law of force from the fact that $\tan \theta = CP/E$ where P is the potential energy of the electron at the point of nearest approach to the scattering particle and E is its initial kinetic energy. C is a factor of proportionality which depends on the power discussed. The above energy relation holds only for small angles of deflection. For an inverse n^{th} power law $\tan \theta = C'/(p^{n-1}V)$, V being the accelerating potential corresponding to the kinetic energy of the electron, and p , the distance of nearest approach. Noticing that all the electrons coming within a circle of radius, p , are scattered at angles greater than θ , one can write immediately for the total current of electrons scattered in all angles greater than θ from a volume of the beam dx cm long at a distance x from the beginning of the path,

$$-dI = I\pi p^2 N dx.$$

If for p^2 is substituted its value from the energy relation and for $\tan \theta$, its value, $a/(L-x)$, the expression becomes, on integration from $x=0$ to $x=L$

$$\log \frac{I}{I_0} = -\frac{K'}{a^{2/(n-1)}} L^{2/(n-1)+1}$$

$$\alpha = K'' \left(\frac{L}{a} \right)^{2/(n-1)}$$

Thus, for an inverse square law α varies inversely with a^2 as previously found. For the inverse fifth power law, $\alpha = k'''(L/a)^{3/2}$. A curve representing this

¹³ O. Beeck, Zeits. f. Physik 61, 251 (1930).

variation of α with a is plotted in Fig. 4. This curve was also arbitrarily made to have the experimental value $\alpha = 16$ for $a = 3$ mm.

Uniform scattering is obtained from the Sommerfeld formula by neglecting $\sin^2 \theta/2$ with respect to α^2 . The α in Sommerfeld's notation should not be confused with the α used as a symbol for the absorption coefficient. When the electron wave-length is long in comparison with the radius of the first Bohr orbit, the expression for the scattering at any distance x from the beginning of the path is:

$$\frac{dI}{I} = -\frac{2\pi}{\alpha^4} \left(\frac{e^2 Z}{4E} \right)^2 N dx \int_{\tan^{-1} a/(L-x)}^{\pi} \sin \theta d\theta = C \left[1 + \frac{L-x}{(a^2 + (L-x)^2)^{1/2}} \right].$$

From this, by integrating over the path one obtains:

$$\log \frac{I}{I_0} = -C(L-a + (a^2 + L^2)^{1/2})$$

or

$$\alpha = \frac{C}{Lp} (L-a + (a^2 + L^2)^{1/2}).$$

For small values of a compared to L

$$\alpha = C'(2 - (a/L)).$$

For molecular hydrogen the coefficient C' is arbitrarily chosen so that $C'(2-a/L)$ is equal to 16 for a 3 mm aperture. The resulting variation of α with aperture for uniform scattering is shown in Fig. 4.

For the numerical case chosen in Fig. 4 the value of Sommerfeld's α is about 0.7. In the above case $\sin^2 \theta/2$ is neglected in comparison with α^2 . When both terms are retained, the dependence of the absorption coefficient on aperture may be found by graphical integration. Fig. 4 shows the curve obtained from the Sommerfeld scattering law adjusted in the same manner as the other curves.

An examination of Fig. 4 shows that the dependence of α on aperture is greatest if an inverse square law of force is assumed and least in the case of uniform scattering as is to be expected. The variation of the experimental points is less than that predicted by the power laws and of the same order of magnitude as that given by the Sommerfeld or the uniform scattering law. The theoretical treatment given here deals only with absorption due to change in the direction of motion of the electron without change in energy. There is also some inelastic scattering which increases the absorption coefficient by an undetermined amount. If an arbitrary constant is added to the coefficients obtained from the scattering laws, any one of the curves can be made to lie within the limits of variation of the experimental points. To do this, however, assuming only scattering due to either an inverse square or fifth power law of force would assume that the scattering was largely inelastic, which is not the case, as we know from previous results. We may conclude, therefore, that the small angle scattering more nearly follows the Sommerfeld law than the inverse power laws, but may be a combination of uniform scattering with that due to some power law.

I am indebted to Professor R. B. Brode for proposing this study and for his continued assistance and interest throughout its progress.

THE RATE AT WHICH IONS LOSE ENERGY IN ELASTIC COLLISIONS

BY AUSTIN M. CRAVATH*

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received May 16, 1930)

ABSTRACT

The rate of energy loss of ions (including electrons) moving through a gas is rigorously calculated on the assumption that the ions and molecules are smooth elastic spheres with no attraction at a distance, having Maxwellian velocity distributions corresponding to the temperatures T_i and T_m respectively. The result is

$$f = \frac{8}{3} \frac{mM}{(m+M)^2} \left(1 - \frac{T_m}{T_i}\right)$$

where m and M are the masses of ion and molecule respectively, T_i and T_m are their temperatures, and f is the average energy loss per collision expressed as a fraction of the average ionic energy.

THERE are a number of problems in which ions (including electrons) move through a gas with an approximately Maxwellian velocity distribution corresponding to a temperature higher than that of the gas, and an expression for the rate at which the ions lose energy in elastic collisions is required. For instance, Compton¹ required it for his electron mobility equation. He deduced an approximate expression as follows. First he calculated the average energy loss for ions of given velocity striking molecules at rest at all angles from grazing to head on. He then corrected this for the motion of the molecules by finding how the energy loss for head on collisions was altered by a (one dimensional) molecular velocity distribution, and multiplying the expression for molecules at rest by this factor. The velocity distribution of the ions was not considered at all. Indeed there *is* no ion velocity distribution if one is merely interested in the average fraction of *its own* energy which an ion loses per collision. What was actually needed, however, was the average energy loss in all collisions expressed as a fraction, f , of the average energy (of all the ions in a given volume). The result obtained was

$$f = 2 \frac{m}{M} \left(1 - \frac{\Omega}{\omega}\right)$$

where m and M are the masses and ω and Ω the average energies of the ions and molecules respectively.

The present paper gives the rigorous calculation of the energy loss on the assumption that ions and molecules are smooth elastic spheres with no attraction at a distance, having Maxwellian velocity distributions.

* National Research Fellow.

¹ Compton, Phys. Rev. 22, 333 (1923).

The symbols which will be used are:

m = mass of ion.

M = " " molecule.

σ = sum of radii of ion and molecule.

T_i = absolute temperature of ions.

T_m = " " " molecules.

k = Boltzmann's constant.

n = number of ions per cm^3 .

N = " " molecules per cm^3 .

V = initial vector velocity of ion.

U = " " " " molecule.

$\mu = M/(m + M)$.

$W = (1 - \mu)V + \mu U$ = velocity of center of mass.

$R = V - W = \mu(V - U)$ = initial velocity of ion relative to center of mass.

D = unit vector giving direction of line of centers, from ion to molecule, at collision.

Q = total energy loss of all ions in 1 cm^3 in 1 sec.

$f = Q / \{(\text{no. collisions per } \text{cm}^3 \text{ per sec}) (\text{average ionic energy})\}$
= average fraction of average energy lost per collision.

To find the total energy loss, Q , we have simply to find the loss in each type of collision and then integrate over all the collisions in 1 cm^3 in 1 sec. A given type of collision is specified by given values of V , U , and D . In a collision, that component of R , the velocity of the ion relative to the center of mass, which is parallel to the line of centers, D , is reversed, and the perpendicular component is unaltered. Hence the final velocity of the ion is

$$V' = V - 2R \cdot DD$$

and the energy lost by the ion is

$$\frac{1}{2}mV^2 - \frac{1}{2}mV'^2 = \frac{1}{2}m\{4V \cdot DR \cdot D - 4(R \cdot D)^2\} = 2mR \cdot DW \cdot D$$

where W is the velocity of the center of mass.

The number of ions per cm^3 with velocity components between V_x and $V_x + dV_x$, V_y and $V_y + dV_y$, V_z and $V_z + dV_z$ is

$$dn = n(m/2\pi kT_i)^{3/2} e^{-mV^2/2kT_i} dV_x dV_y dV_z$$

where n is the number of ions per cm^3 and T_i is their temperature. Similarly, the number of molecules per cm^3 with given velocity is

$$dN = N(M/2\pi kT_m)^{3/2} e^{-MU^2/2kT_m} dU_x dU_y dU_z.$$

The number of collisions per cm^3 per sec. between ions and molecules of the above velocities in which the line of centers at impact lies within the solid angle $d\omega$ about the direction D is

$$dndN(V - U) \cdot D\sigma^2 d\omega = dndN(1/\mu) R \cdot D\sigma^2 d\omega$$

where σ is the sum of the radii of ion and molecule. The energy loss per cm^3 per sec. in these collisions of the given type is

$$(2mR \cdot DW \cdot D) \left\{ n(m/2\pi kT_i)^{3/2} e^{-mV^2/2kT_i} dV_x dV_y dV_z \right\} \\ \times \left\{ N(M/2\pi kT_m)^{3/2} e^{-MU^2/2kT_m} dU_x dU_y dU_z \right\} (\sigma^2/\mu) R \cdot D d\omega.$$

Fig. 1.

D may be expressed in polar coordinates ϕ and ϑ (Fig. 1) with the axis parallel to R and the plane $\phi=0$ containing W . Then

$$d\omega = \sin \theta d\phi d\theta$$

$$R \cdot D = R \cos \theta$$

$$W \cdot D = W \cos \chi = W(\cos \theta \cos \psi + \sin \theta \sin \psi \cos \phi)$$

and the total energy loss per cm^3 per sec. becomes

$$Q = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_0^{2\pi} \int_0^{\pi/2} (2mnN\sigma^2/\mu) (m/2\pi kT_i)^{3/2} (M/2\pi kT_m)^{3/2} \\ e^{-mV^2/2kT_i - MU^2/2kT_m} R^2 W \cos^2 \theta \sin \theta \\ (\cos \theta \cos \psi + \sin \theta \sin \psi \cos \phi) d\theta d\phi dV_x dV_y dV_z dU_x dU_y dU_z$$

in which R , W , and ψ are all functions of $V_x \dots U_z$.

The integrations with respect to θ and ϕ may be performed immediately. For the remaining six integrations, V and U are replaced by R and W , expressed in polar coordinates. The result is

$$Q = 8(2\pi)^{1/2} n N \sigma^2 k^{3/2} \{mM(mT_m + MT_i)\}^{1/2} (m+M)^{-2} (T_i - T_m).$$

Finally, f , the average energy loss per collision expressed as a fraction of the average energy of the ions, is equal to Q divided by the number of collisions per cm^3 per sec. all divided by the average energy:

$$f = Q / \left\{ \left[n N \pi \sigma^2 \left(\frac{8kT_i}{\pi m} \right)^{1/2} \left(\frac{m}{M} \frac{T_m}{T_i} + 1 \right) \right] \left[\frac{3}{2} kT_i \right] \right\} \\ = \frac{8}{3} \frac{mM}{(m+M)^2} \left(1 - \frac{T_m}{T_i} \right).$$

METHOD OF ENHANCING THE SENSITIVENESS OF
ALKALI METAL PHOTOELECTRIC CELLS

BY A. R. OLPIN

BELL TELEPHONE LABORATORIES

(Received June 6, 1930)

ABSTRACT

A technique is described for sensitizing alkali metal photoelectric cells to light by introducing onto the metal surface small amounts of dielectrics, as oxygen, water vapor, sulphur vapor, sulphur dioxide, hydrogen sulphide, air, sodium bisulphite, carbon bisulphide, etc., or some organic compound as methyl alcohol, acetic acid, benzene, nitrobenzene, acetone, etc., or some organic dye as tropaeolin, rosaniline base, eosin, cyanine, kryptocyanine, dicyanine, neocyanine, etc. The marked increase in electron emission from the cathodes of cells so treated is due primarily to an increase in response to red and infrared light. Vacuum sodium cells have been produced, yielding photoelectric currents as high as 7 microamperes per lumen of white light of color temperature 2848°K and caesium cells yielding far greater currents.

The response of these cells is proportional to the intensity of the exciting light even for light of longer wave-lengths than that to which the cell responded before treatment.

Spectral response curves are similar for all cells using the same metal as cathode. These curves differ from the curves for the pure metal by the appearance of a new selective maximum at lower frequencies. This newly appearing maximum resembles the regular maximum for the untreated metal and is always separated from it by the frequency of a well-known line in the vibration-rotation spectrum of the dielectric molecules, usually the 1.5μ line so characteristic of oxygen-hydrogen, carbon-hydrogen or nitrogen-hydrogen linkages. The long wave limit shifts an amount agreeing with the separation of the maxima.

With a cell so designed that the cathode could be sensitized in a side chamber and then slipped into its proper place (thus keeping the anode free from light-sensitive materials), stopping potentials were obtained for electrons, liberated by monochromatic light, from a sodium cathode before and after treating it with sulphur vapor and air. For light of wave-lengths ranging from $\lambda 3500\text{\AA}$ to $\lambda 8000\text{\AA}$ falling on the treated cathode, the electron retarding potentials are found to vary linearly with the frequency of the exciting light, thus establishing the validity of Einstein's photoelectric equation for composite surfaces. From the slope of the straight line depicting this relationship, the value of Planck's constant h is found to be 6.541×10^{-27} , significant to three figures. An almost identical value is obtained for untreated sodium. The apparent stopping potentials, or voltages at which the photoelectric currents become zero are the same before and after the sulphur and air treatment. The voltage at which the current just saturates is always greater after treatment than before. This is a measure of the change in contact potential of the cathode due to the presence of the sulphur and air. Changes of approximately 0.8 volts are common.

The validity of Einstein's equation precludes the possibility of explaining the new maximum in the spectral response curve for a treated surface by a "Raman shift" of the incident light frequencies, even though the separation of these maxima is equal to certain well-known vibration-rotation frequencies of the dielectric molecules. It may be that the natural frequency of the alkali metal atom is diminished by the vibration frequency of the complex atom in which it is incorporated.

The Lindemann formula for the frequency of the selective photoelectric maximum [$2\pi\nu = (ne^2/mr^3)^{1/2}$], primitive though it seems in the light of modern theory, has always given values for the pure metals in close agreement with experimental determinations. The n term is determined by the valence of the substance, a choice of unity being used for the monovalent alkali metals corresponding to an electron revolving around a singly charged ion. A choice of 2, 3,—for divalent, trivalent,—substances corresponds to electrons revolving around doubly, triply—charged ions. Under certain conditions the alkali metals manifest different valencies, such for instance, as those exhibited in the oxide series Na_2O_2 , Na_2O , Na_3O , Na_4O . These compounds can be prepared in vacuum and are light-sensitive. Spectral response curves for such cells exhibit all the selective maxima called for by the Lindemann formula when the value of n is chosen to agree with the valence of the metal. Data are presented showing this condition to be general for the alkali metals, a maximum response to red or infrared light being dependent upon the formation of a subvalent compound, as a suboxide.

Attention is called to seemingly analogous phenomena in the fields of photoelectricity, photography, fluorescence and absorption.

THE work which culminated in the results to be reported in this paper was inspired by the simple inference that, since photoelectric emission from potassium is greatly increased by a non-conducting hydride film on the surface,^{1,2} some other dielectric film might be still more effective in the same sense. As will be seen the consequences were far-reaching. Not only have far more sensitive photoelectric cells been developed but their characteristics have been studied sufficiently to throw some light on the cause of the increase. Moreover, the results of the rather extensive research suggest plausible explanations of various phenomena in the fields of absorption, photoelectricity, fluorescence and photography.

A. APPARATUS FOR MEASURING PHOTOELECTRIC CURRENTS

The response of photoelectric cells to unresolved light was always measured on a high sensitivity Leeds and Northrup galvanometer, a system of external shunts being used to lower the sensitivity as the magnitude of the photoelectric currents increased. Currents as small as 10^{-10} amperes could be conveniently determined in this way with the instrument on which the largest currents obtainable were measured.

The photoelectron emissions for highly resolved light, represented by the ordinates of the spectral response curves which follow, were measured by a Compton quadrant electrometer using a resistance leak of the order of 10^4 megohms. By suitably adjusting the needle voltage, steady deflections were easily readable for currents as small as 10^{-14} amperes.

The source of light was usually a glowing tungsten filament of horizontal candle power about 70 and color temperature 2848°K . To resolve or disperse this light, a high precision Hilger monochromator was used. Proper corrections for the dispersion of the prism were made. All data plotted in the spectral response curves of this paper represent current per unit energy of the incident light, unless otherwise specified.

B. SENSITIZATION OF CELLS WITH VAPORS FROM SULPHUR

1. *Potassium surfaces.* The first experiment with dielectric films on light sensitive cathodes was performed by admitting sulphur vapor to a potassium surface in vacuum. The technique involved in the manufacture of these cells is given here as typical of that for all the cells made and used throughout the series of tests herein reported, except where otherwise specified.

A glass bulb of the shape shown in Fig. 1. was connected to a vacuum pump by means of a distilling tube, in a side chamber of which was a slug of previously distilled potassium. In the center of the cells was a metallic

Fig. 1. Experimental type photoelectric cell. *A*-Ring-shaped anode. *B*-Bulb coated on inside with alkali metal to form cathode. *C*-Liquid air trap. *D*-Side arm containing dielectric.

ring *A* with a wire leading through the glass walls to form an anode. A lead-in wire came through the bottom of the cell to make contact with the potassium when it was deposited on the glass walls. A small glass tube *D* containing ordinary commercial flowers of sulphur was sealed onto the stem of the bulb. The U-shaped section *C* of this tube could be immersed in liquid air to trap the vapors coming from the sulphur.

After thorough evacuation of the system, the potassium in the distilling tube was melted and then distilled against the suction of the pump into the glass bulb and a coating made on the inner walls *B*. With a point flame a clear space about one inch in diameter for admitting the exciting light was made on the side of the bulb. As the light fell on the potassium surface, a galvanometer in series with the cell showed that a steady, though limited, emission of electrons was going on. The side tube containing sulphur was then heated and a very small amount sublimed onto the potassium coating.

The pump was left running during this treatment. The galvanometer registered an increased emission of electrons almost immediately and this continued until a certain critical amount of sulphur vapor had come in contact with the surface after which the number of electrons liberated by the light, began rapidly to decrease.

Table I gives a typical history of the treatment of a potassium surface with sulphur vapor, showing the relative current values for two different polarizing voltages at every stage in the process.

TABLE I.

Cathode History	P.E. Current at Cathode Voltages	
	-8	-50
Freshly distilled potassium	34.	38.
After admitting a trace of sulphur vapor	179.	217.
After admitting more sulphur vapor	905.	424.
Incident light diffused by ground glass	542.	542.
Slightly more sulphur admitted	840.	386.
Sulphur tube sealed off	846.	418.
Very low pressure of Argon	1360.	2280.
Argon pressure increased to 0.1 mm	1470.	4120.

It was noted that once the dielectric film began to build up, as shown by a change in the surface color, the current values were larger at low voltages than at high. This has been quite generally observed with this type cell, the voltage-current curves showing a maximum sometimes at cathode voltages as low as -5 volts. This maximum disappeared with the introduction of argon into the cell, and a general increase in measurable current even at low voltages was noted. A typical series of voltage current curves for a potassium surface treated with sulphur vapor is shown in Fig. 2. Another series for a rubidium cell similarly treated is reproduced in Fig. 3. The irregularities exhibited in these curves could be smoothed out by focusing the incident light on the side of the cell rather than the back, or by passing it through a diffusing glass. This suggested that they were due to the shape or design of the tube, an interesting observation which will be further discussed in a later section of this paper.

TABLE II.

Color of exciting light	EK filter used	KSH cell	KS cell	KH cell
White	None	374	374	374
Violet	#76	11	11	20
Blue	#78	93	101	132
Green	#60	59	85	44
Yellow	#16	120	72	9
Red	#29	58	11	1

It developed early in the work that the photoelectric emissions from potassium surfaces treated as described above were not only greater than those of potassium hydride cells for unresolved light, but the response to red light was decidedly larger. Even more striking results of this character were

obtained in some cases by flashing hydrogen on the surface treated with sulphur. Table II illustrates the relative sensitivities to colored light on a scale in which the emissions under the action of total light are made equal. The letters used to describe the cells refer to the elements known to be present at the cathode surface.

Fig. 3.

Fig. 3. Voltage-current curves for a rubidium-sulphur vapor photoelectric cell containing different pressures of argon. 1 Vacuum condition. 2—6 Argon pressure gradually increased.

The color temperature of the constant light source used in the preparation of this table was not known, but Fig. 4 shows the relative sensitivities of KH and KS cells to white light of color temperature 2848°K. The new cells were very stable and showed little change in emission upon aging, the tendency being rather frequently to increase slightly in sensitivity during the first few days after sealing off the pump. In Fig. 5 are plotted some curves showing relative sensitivities throughout the spectrum. These curves, taken with spectrally resolved light, are corrected so that the ordinates, representing current per unit of light energy incident on the surface, are equal at the selective maxima.

It will be noted that the large selective maximum for each of these curves lies in the blue-violet region of the spectrum but that the maximum for the potassium-sulphur cell is slightly displaced toward shorter wave-lengths. The long wave end of the curves for this cell can be represented as an amplified sensitivity curve for pure potassium plus an additional curve representing a new maximum symmetrically drawn about 6200Å. This maximum could be greatly enhanced by proper treatment and its importance should not be overlooked. It falls in that portion of the spectrum where the energy content of radiations from most illuminating systems is large, and its pres-

Fig. 4.

Fig. 5.

Fig. 5. Spectral response curves for potassium, potassium-hydride and potassium-sulphur vapor photoelectric cells.

ence figured strongly in increasing the response of a cell to white light. Further discussion of this part of the curve will be reserved for a subsequent section of this paper.

2. *Rubidium and caesium surfaces.* Encouraged by the increase in response to red light manifested by potassium cells treated with sulphur vapor, the same treatment was applied to rubidium and caesium. Since the selective maxima³ and the long wave limits⁴ for these two alkali metals are or-

³ F. Gross, *Zeits. f. Physik* 7, 316 (1921).

⁴ B. Gudden, "Lichtelektrische Erscheinungen" p. 40 Julius Springer, Berlin (1928).

dinarily found at greater wave-lengths than for potassium, it was thought that surfaces of these metals, treated as above, should yield electrons more freely than potassium when excited by red or infrared light. However, disappointment in this respect attended all early efforts, presumably because the low melting points and high vapor pressures of rubidium and caesium would not permit the formation of a definite surface structure. The results illustrated for a treated caesium film in Fig. 6, differ only from what would be expected with a pure caesium film by the presence of a maximum between 5000Å and 5500Å. This is the wave-length region at which caesium in bulk form has been observed to manifest a selective maximum.⁵

Fig. 6.

Fig. 6. Spectral distribution of sensitivity for a caesium film on magnesium plus sulphur vapor.

Fig. 7.

Fig. 7. Spectral distribution of sensitivity for a specially treated caesium photoelectric cell. Curves (a) and (b) were obtained from cells treated to give maximum response to red light. Curve (c) was obtained on a similar cell having less red sensitivity.

Early difficulties in treating caesium surfaces effectively with gases have in great measure been overcome by subsequent development of a technique for controlling the amounts of the various constituents which make up the cathode, so as to form the proper compounds. The rather remarkable results obtained with these cells supplement the data contained in this paper and will constitute the subject of a later publication. Suffice it to say that the photoelectric yield for properly treated caesium cathodes is almost entirely due to a marked response to deep red and infrared light, as shown in Fig. 7.

⁵ E. F. Seiler, *Astrophys. J.* 52, 3, 129 (1920).

3. *Sodium surfaces.* The difficulties which arose in connection with the manufacture of rubidium and caesium cells suggested the advisability of using sodium as the photosensitive material. It was found in fact that when sodium was treated similarly with sulphur vapor, photoelectric cells were evolved having much greater sensitivity than the potassium-sulphur cells previously described. Moreover, the cause of this was found to be increased response to light at the long wave end of the visible spectrum and in the infrared.

Fig. 8 shows a typical curve giving photoelectric current per unit of exciting light energy for such a cell throughout the spectrum. The maxi-

Fig. 8.

Fig. 9.

Fig. 9. Relative sensitivity of potassium hydride, potassium-sulphur vapor and sodium-sulphur cells throughout the spectrum.

mum at $\lambda 3600\text{Å}$ should probably appear at a slightly shorter wave-length as it is likely that some absorption of the incident light by the glass walls of the cell occurs below $\lambda 3800$ or 4000Å . However, the fact that Richardson and Compton⁶ found this maximum at $\lambda 3600\text{Å}$, and Pohl and Pringsheim⁷ at $\lambda 3400\text{Å}$ shows that the peak had not been shifted appreciably by the treatment with sulphur vapor. It was the appearance of a new maximum at approximately $\lambda 4800\text{Å}$ that was most significant. In Fig. 9 are found three curves comparing the spectral response of a sodium-sulphur cell with that of two types of potassium cell.

⁶ O. W. Richardson and K. T. Compton, *Phil. Mag.* 26, 549 (1913).

⁷ R. Pohl and P. Pringsheim, *Verh. d. D. Phys. Ges.* 14, 46 (1912).

By applying a point flame momentarily near the edge of the cell window and temporarily producing a vapor of the sodium and the gas occluded on it, a startling increase in sensitivity was brought about. The response of the surface to white light of color temperature 2848°K after this last treatment was about double that observed before. Moreover, the increase was again chiefly in the red and infrared regions, as shown in Fig. 10. The new spectral emissivity curve could be broken up into a regular curve for sodium greatly amplified plus a new curve with a pronounced maximum at approximately

Fig. 10.

Fig. 10. Spectral response curve for sodium-sulphur vapor cell after deposition of a film of the mixture on the surface.

Fig. 11.

Fig. 11. Curves analyzing the increased sensitivity of sodium-sulphur vapor cells throughout the spectrum.

$\lambda 4800\text{Å}$. In Fig. 11 is found a record of the spectral distribution of emissions for each step in the sensitizing process.

At this stage in the development of these cells, air at atmospheric pressure was admitted onto the surface. Upon re-evacuation the cell showed absolutely no response to light of any color. By applying a point flame near the edge of the cell window momentarily and producing a vapor of sodium plus the adsorbed gases, a film deposited on the cathode surface which was strikingly sensitive to light. This experiment has been repeated with many

cells and the same effect always occurs. It appears that the effect is a broadening of the new selective maximum on the long wave side with a shift of the long wave limit to approximately 1μ , as shown in Fig. 12. Fig. 13 shows that

Fig. 12. Curves showing spectral distribution of sensitivity and long wave limits for sodium-sulphur-air cell. Actual electrometer readings are plotted in the broken curve, and current per unit energy in the so-called equi-energy curves.

pure Na surfaces can be sensitized to light of long wave-lengths by air and oxygen alone, but comparison with Figs. 12 and 14 indicates the advantage of the presence of sulphur vapor.

Fig. 13. Spectral response curves for sodium photoelectric cells treated with oxygen and air alone.

In Fig. 15 are given voltage-current curves for a typical potassium cell treated with sulphur vapor, a sodium cell similarly treated, another such

sodium cell with a thin film deposited on top of the dielectric, and finally a sodium cell treated with both sulphur vapor and air as described above. None of these cells were gas filled so the ordinates represent true emissions from the surface. These emissions are in terms of microamperes per lumen, and the color temperature of the exciting light was 2848°K.

C. PROPORTIONALITY OF RESPONSE TO LIGHT

The relationship between the light intensity and photoelectric current was checked over an extensive range for both potassium and sodium surfaces sensitized by the methods described above. The results are depicted by the straight lines in Fig. 16. The variations in light intensity were effected by moving the lamp source along a photometer track. The measurements were made on a Compton electrometer, using the steady deflection method. The same linearity of response was noted when using a No. 87 EK filter (visually opaque) in the path of the light. This filter transmitted only light of greater wave-length than that to which the pure metals respond.

D. ATTEMPTS TO IDENTIFY THE ACTIVATING GAS IN THE VAPORS FROM SULPHUR

The words "sulphur vapor" have been used advisedly in the foregoing presentation, for it was early discovered that the actual sublimation of sulphur onto the surface was not essential. In fact, equally good cells were made with only the volatile gases liberated from sulphur on heating. These gases could be held in a liquid air trap between the sulphur and the cell, and then by lowering the liquid air flask properly, the amount of gas actually entering the coated cell could be accurately controlled.

Fig. 17. Spectral response of a potassium photoelectric cell into which an unnoticeably small amount of vapor from sulphur had passed.

A surprising observation was that vapor in such small quantities as to be scarcely detectable with an ionization manometer gauge began to increase the sensitivity as soon as it entered the cell. In a way this was a fortunate discovery, for the amount of gas actually occluded or contained in commercial flowers of sulphur was decidedly small. Yet when a potassium cell with a side arm containing sulphur was sealed off the pump station, and a curve taken showing the spectral distribution of response to light (Fig. 17),

there was appreciable sensitivity out to 1μ . Evidently some gas had been liberated from the sulphur, but the amount was too small to be detected. This emphasizes the importance of taking added precautions against the presence of gas on surfaces to be used in determining the long wave limits of pure alkali metals, and suggests the likely cause for the wide discrepancies sometimes found in literature.

The question as to the nature of the activating gas contained in sulphur was a challenging one since that gas was present in such small quantities.

Fig. 18.

Fig. 18. Spectral response of potassium photoelectric cells, the cathodes of which were treated respectively with hydrogen, sulphur vapor, sulphur dioxide, hydrogen sulphide, water vapor, oxygen and sulphur vapor, tellurium vapor, phosphorous vapor and iodine vapor. The ordinates at the maximum are made equal.

Fig. 19.

Fig. 19. Spectral distribution of sensitivity of sodium photoelectric cells treated with hydrogen, sulphur vapor, oxygen, selenium vapor, sulphur-dioxide, water vapor, oxygen and sulphur, and selenium and sulphur with air. These curves are corrected to correspond at approximately 3500 Å.

It certainly was not air, hydrogen, nitrogen or oxygen, for these gases could not be condensed at liquid air temperatures. It therefore seemed plausible to suppose that it was water vapor, hydrogen-sulphide or sulphur-dioxide; and direct tests were made to find how these gases act.

A large number of potassium and sodium cells were made, the coating of each being treated with one of the mentioned gases. All of the spectral response curves for potassium cells had selective maxima in the blue at

approximately the same wave-length, and the long wave limit did not vary appreciably from one cell to another. The gas producing results on potassium most nearly like those observed when using sulphur vapor was SO_2 , the only one to give the bright golden color and the one producing the most sensitive surfaces to unresolved light.

In Fig. 18 curves depicting the spectral distribution of electron emission are given for potassium cells sensitized with sulphur vapor, sulphur dioxide, hydrogen sulphide, water vapor, sulphur vapor plus oxygen, tellurium vapor, phosphorous vapor and iodine vapor. In all these cases it will be noticed that the selective maximum appeared at approximately the same wave-length, but generally was shifted to somewhat smaller values when sulphur

Fig. 20. Spectral response of sodium cell treated with sodium-bisulphite vapor.

was present in the activating gas. We thus find nothing to support Wiedmann's idea⁸ that the position of the maximum varies with the nature of the gas. It may be, however, that the relative *magnitudes* of the newly appearing maxima are influenced by the composition of the surface films.

With sodium the different gases produced markedly different curves (Fig. 19) and this gives us a better chance of identifying the vapor proceeding from the sulphur. In this case, it turned out that water vapor yielded the curve most resembling that due to the sulphur vapors, and incidentally colored the surface with a similar tint (dull grey); while sulphur dioxide alone provided a very different curve.

There seemed only one conclusion to draw from these tests. The activating vapor liberated from commercial flowers of sulphur must have been

⁸ G. Wiedmann, Verh. d. D. Phys. Ges. 16, 343 (1915).

a combination of water vapor and sulphur dioxide,⁹ and the dielectric films formed must have been sodium and potassium bisulphites. This conclusion seemed the more plausible when it was recalled that the sulphonc radical $\text{SO}_2 \cdot \text{OH}$ is an important radical in many organic dyes, and that investigators in the Eastman Research laboratory have succeeded in sensitizing photographic plates to light well into the infrared by the use of sodium bisulphite NaHSO_3 .¹⁰ A sodium cell was therefore made substituting sodium bisulphite for sulphur, and the spectral response of this cell (Fig. 20) was very similar to that obtained with sulphur and air. Moreover, the response was in almost identically the same spectral region to which the photographic plate treated with NaHSO_3 responded. The close correlation between these results in the fields of photoelectricity and photography suggests a common cause of the red sensitivity.

E. SENSITIZATION OF SODIUM AND POTASSIUM SURFACES BY ORGANIC DYES

There was no reason to suppose that sodium bisulphite is the only substance used in photography which could be applied in photoelectricity. Accordingly, other sensitizing dyes were introduced onto the light sensitive surfaces of alkali metals, and marked increases in photoelectric emission noted. In every case the amount of dye required was very small, as in plate sensitizing. The colors appearing on the cathode surfaces especially when thin films of sodium and potassium were added on top of the already treated surfaces were varied and beautiful.

Some of the side tubes containing the dyes had to be immersed in liquid air to prevent vaporization with possible decomposition under action of the pump. Others had to be warmed before they sublimed, and in such cases it is not only possible but likely that partial chemical decomposition occurred. In fact, Herndon and Reid's¹¹ study of the decomposition products of various alcohols, organic acids, acetates, benzenes, phenols, etc. upon heating to 400° suggests that the more complicated compounds break up into simple ones at considerably lower temperatures. Nevertheless, the well-known organic radicals which produce the absorption bands in the visible region, as the methyl group CH_3 , the nitroxyl group NO_2 , the amido group NH_2 , the bromine group, the methoxyl group CH_3O , the carboxyl group $\text{CO} \cdot \text{OH}$ and the sulphonc group SO_2OH , and many others probably are fairly stable.

The first dyes used contained the sulphonc radical and are not commonly used in photography. They were kept in a side tube beyond a liquid air trap, and heated after the alkali metal coating was made. When they were first heated, some gas passed through the liquid air trap into the cell and was

⁹ More recently Dr. G. T. Kohman of the Bell Telephone Laboratories has made a very ingenious analysis of the gases evolved from flowers of sulphur on heating and found water vapor and sulphur dioxide to be contained in greatest amounts, with also considerable hydrogen sulphide.

¹⁰ Capstaff and Bullock, *Brit. J. Phot.* **67**, 719 (1920).

¹¹ L. R. Herndon and E. E. Reid, *J.A.C.S.* **50**, 3066 (1928).

pumped out. This was probably nitrogen, hydrogen, or dry oxygen, or possibly some hydrocarbon compound, for it did not react with the alkali metal. The gas retained in the liquid air trap was very effective in sensitiz-

Fig. 21. (a) Spectral response curves for sodium photoelectric cells treated with the vapors of tropaeolin 000 No. 1 and sodium indigo disulphonate.

ing the metallic surface of the cell when allowed to enter in small quantities. A very thin film of the alkali metal deposited on the colored surface always enhanced the emission. In Fig. 21(a) are curves showing the response, in

Fig. 21. (b) Spectral response curves for potassium photoelectric cells treated with the vapors of tropaeolin 000 No. 1 and sodium indigo disulphonate.

the visible and infrared, of sodium cells treated with the isomeric compounds tropaeolin 000 No. 1 [$\text{HO} \cdot \text{C}_{10}\text{H}_6 \cdot \text{N} : \text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{SO}_3\text{Na}$] and sodium indigo disulphonate. Both compared favorably with the sodium-sulphur air cells

described in a previous section. Curves for the corresponding potassium coated cells, using these dyes, are given in Fig. 21(b).

To determine whether or not the sensitizing action was limited to compounds containing sulphur, a cell was made with rosaniline base $[\text{OH} \cdot \text{C}$

Fig. 22. Spectral response curve for a sodium cell treated with rosaniline base.

$(\text{C}_6\text{H}_4\text{NH}_2)_3]$ and a sodium coating. Although no sulphur was contained in this compound, the surface treated showed a good response to light throughout the visible and near infrared, as shown in Fig. 22.

Fig. 23. Spectral response curve for a potassium photoelectric cell treated with eosin blue.

The remainder of the experiments to be reported in this section involve sensitizing dyes used in photography. Because of its historical importance, (it was first used to sensitize photographic plates to green and yellow light

in 1882) eosin [$C_6H_4(COC_6H_4ONa)_2O$] was tried first. Although it brought about a decided increase in sensitivity, it was not so satisfactory as many

Fig. 24. (a) Spectral response curves for a potassium photoelectric cell treated with alizarine blue alone and one treated with alizarine blue plus ammonium sulphite.

others. In Fig. 23 is reproduced a spectral distribution curve for a potassium-eosin cell, showing the presence of the new maximum at longer wave-lengths very strikingly. The peculiar shape of the regular selective maximum will

Fig. 24. (b) Spectral response curve for a sodium photoelectric cell treated with alizarine blue and ammonium sulphite.

be cited again in the discussion to follow. There appears to be a new peak at a slightly shorter wave-length.

Some have claimed astonishing results in sensitizing photographic plates to red by using alizarine blue [$C_{17}H_{11}NO_{10}S_2Na_2$];¹² and plates treated in addition with ammonia, have been reported sensitive out to about 1μ . In Fig. 24(a) is found a typical photoelectric emission curve for a potassium coating treated with alizarine blue and another curve for potassium treated also with the vapor from ammonium sulphite (NH_4SO_3). In Fig. 24(b) is a curve for sodium similarly treated. These curves show a response to light of all wave-lengths under 1μ , with the new maxima appearing at the same position as for the sulphur vapor cells. Here again is a close correlation between results obtained in the sensitizing of photoelectric cells and photographic plates.

Similar results attended the use of dicyanine, especially with addition of ammonium sulphite, and other dyes carrying the latter part of the same word

Fig. 25. Curve showing strikingly broad selective maximum in the spectral response curve for a sodium photoelectric cell treated with kryptocyanine.

in their trade names, as kryptocyanine and neocyanine. The spectral regions wherein these dyes are effective sensitizers of photographic plates is published in communication No. 255¹³ of the Eastman Research Laboratories where the latter two dyes were developed. Kryptocyanine should be better in the near infrared than dicyanine which in turn should be better than cyanine ($C_{29}H_{35}N_2I$). All of these indications were borne out on photoelectric cells, the dicyanine causing a greater electron emission from alkali metal surfaces than cyanine, and very small amounts of kryptocyanine producing one of the broadest selective bands so far observed in the spectral distribution curve for sodium cells. This last mentioned curve is found in Fig. 25.

F. SENSITIZATION BY COLORLESS DIELECTRICS

The position of the new maximum seems to be characteristic of the light sensitive metal and not the dielectric on its surface. It appeared likely,

¹² Scoble, Phot. J. **46**, 190 (1906).

¹³ M. L. Dundon, A. L. Schoerr, R. M. Briggs, J.O.S.A. and R.S.I. **12**, 397 (1926).

therefore, that any dielectric regardless of the peculiarities of its absorption spectrum, might bring out such a maximum. To test this, various colorless dielectrics and dielectrics practically transparent to visible light were substituted for the dyes. Most of these were liquids, but their vapors could easily be held in side tubes by means of liquid air. The technique employed in applying them was identical to that for the dyes.

Acetone ($\text{CH}_3 \cdot \text{CO} \cdot \text{CH}_3$), *acetic acid* ($\text{C}_2\text{H}_4\text{O}_2$), *carbon bisulphide* (CS_2), *methyl alcohol* (CH_3OH), *carbon tetrachloride* (CCl_4), *benzene* (C_6H_6), *chloroform* (CHCl_3), *phenyl mustard oil* ($\text{C}_6\text{H}_5\text{-N-C=S}$), *nitrobenzene* ($\text{C}_6\text{H}_5\text{NO}_2$), and *water-vapor* (H_2O) were used with more or less success. And surprising though it may seem, benzene and water vapor were the most effective, the red sensitivity of sodium surfaces properly treated with them being especially

Fig. 26. Spectral response curves for sodium photoelectric cells treated with water vapor and with benzene.

marked, as shown in Fig. 26. There was absolutely no evidence of chemical action when benzene was admitted to the cell, even though a thin film of sodium was deposited on top of it. In fact, the surface of the completed photoelectric cell looked exactly like that of pure metallic sodium. This, of course, is not surprising since the alkali metals are preserved in benzene, but is cited here as evidence of the chemical purity of the sample used. In quite striking contrast to the behavior of benzene on sodium was that of water vapor, whose powerful affinity for the alkali metals makes it necessary to preserve them in benzene, oil, or sealed air-tight containers. Yet benzene and water vapor were alike in being able to increase photoelectron emissions from sodium and potassium surfaces.

In every case mentioned in the preceding paragraph, except that of CCl_4 , an appreciable amount of sensitivity to red was developed. Moreover, the

Fig. 27. Spectral response curves for sodium photoelectric cells treated with carbon bisulphide and with carbon tetrachloride.

Fig. 28. Peculiarities noted in voltage-current curves for a sodium-carbon bisulphide photoelectric cell. 1—Supposedly pure sodium. 2—After first introduction of CS_2 on sodium surface. 2R—Same as 2 but for irradiation with red light only. 3—After additional CS_2 was introduced onto the surface. 4—After a film of sodium had been deposited from near the cell window. 4R—Same as 4 but for illumination with red light only. 5—Light focussed on cathode opposite cell window. 6—Light focussed on cathode adjacent cell window.

spectral distribution curves show evidence of a new maximum in the photoelectric emission curve near $\lambda 4800\text{\AA}$ for sodium and a much less pronounced peak at approximately $\lambda 6200\text{\AA}$ for potassium. When carbon tetrachloride was used no deflection of the galvanometer was observed when the exciting light was passed through a red filter, cutting out all wave-lengths under 6000\AA . In Fig. 27 are plotted wave-length vs. current curves for sodium surfaces sensitized with carbon tetrachloride and carbon bisulphide.

When working with carbon bisulphide (CS_2) and nitrobenzene ($\text{C}_6\text{H}_5\text{NO}_2$) the previously described peak in the voltage-current curve at low voltages was strikingly prominent. At one time during the treatment of sodium with CS_2 the current output with the cathode 15 volts negative was four to five times its value when this voltage was increased to 100 volts. A record of the change in shape of these curves as the sensitization process was carried out is included in Fig. 28. These will be discussed with those in Fig. 2 and 3 in the next section.

G. DISCUSSION OF RESULTS

A great mass of data has been presented. It now remains to be seen whether or not they can be correlated and interpreted. In all, over two hundred photoelectric cells involving the principles and technique herein discussed have been made, and most of them carefully studied. The collection of curves presented in the preceding sections of this paper may or may not in

Fig. 29. Spectral response curves for the alkali metals. Curves for sodium and potassium reproduced from Pohl and Pringsheim⁷ and those for rubidium and caesium from Miss Seiler.⁵

every case refer to the best cell which could possibly be made with the stated materials; but they do display the properties of the cell when made according to the best technique at that time known.

A survey of the data presented in the form of spectral response curves revealed that the properties of the cells depended very much on the metal, very little on the dielectric. As pointed out previously (Fig. 11) each curve could be represented as the sum of the "regular" curve for the pure metal and a second curve with a maximum at longer waves. Only the *relative magnitudes* of the ordinates of these two curves seemed to be a function of the

dielectric. The so-called "regular" curves for the pure alkali metals are shown in Fig. 29. Each one will be seen to resemble a resonance curve, the area underneath being more or less symmetrically located on either side of the wave-length of light producing the greatest photoelectric current. These curves are not alone characteristic of the multiply distilled metals, but are also characteristic of these metals after a glow discharge has been passed through hydrogen at a pressure of a few millimeters on the surface. This fact caused Pohl and Pringsheim¹⁴ to refer to the metallic hydride surfaces as colloidal metal surfaces and attribute the increased response of such surfaces to light to the greater ease with which electrons might escape from tiny globules. This same fact caused Hallwachs and Wiedmann¹⁵ to claim that the photoelectric effect was a gas-metal phenomenon and that the maxima in the curves shown in Fig. 29 were dependent on the presence of hydrogen. At this stage in our discussion it is the *existence* of these maxima in the "regular" curves rather than the *cause* to which attention is called.

The "second" curve referred to above appeared as the "regular" curve shifted to longer wave-lengths. The amount of this shift was approximately the same for all cases excepting the ones in which sulphur or selenium plus oxygen or air and certain organic dyes, as kryptocyanine, were among the activating agents, in which cases it was somewhat greater, and the new maximum broader, as illustrated in Fig. 19. Slight variations in the separations of the two maxima, when several dielectrics were used, were dependent on the relative amounts of the different materials.

1. *Role of water vapor.* This analysis of the spectral response curves suggested that there is a single activating agent common to all the dielectrics introduced onto the alkali metal surfaces, with the possibility of one or more others in a few cases. Certainly it must be conceded that water vapor may have been present in every case. Every effort was made to eliminate it, the glass bulbs being carefully and thoroughly heated during the evacuating process. But, as mentioned earlier, the substances which were evaporated or sublimed onto the cathodes may have contained water. The glass tubes containing them could not be heated sufficiently to drive out all moisture before the alkali metal coatings were made. With liquids, it was necessary to immerse the side arm containing them in liquid air to keep them from evaporating and being pumped out. Moreover, the bulky, complex organic dye compounds usually occur in the form of very fine crystalline granules, undoubtedly containing water in small quantities. Some of the substances may have decomposed with formation of water vapor. There was no assurance that the samples of liquid dielectrics were absolutely water free, even though they were obtained from a reliable chemical house as certified chemically pure material. Take, for instance, benzene, a liquid easily obtained as "chemically pure" yet Manley¹⁶ reports experiments which seem to

indicate that benzene, when exposed to air, takes up moisture and holds it tenaciously. Certainly, the difficulties involved in handling liquids in an evacuated system make it impossible to eliminate water vapor altogether from the system.

Although the amount of water that could have been present with the dielectric was admittedly always small, it may not have been negligible. As a matter of fact, many of the experiments seemed to indicate that even *minute traces of moisture* were sufficient to sensitize alkali metal surfaces. One experiment consisted in sealing an empty glass tube on the side of a bulb and then during the pumping process immersing the tube in liquid air. After the bulb was coated, mere removal of the liquid air from the side tube permitted sufficient moisture to fall onto the metal coating to increase its response greatly. The characteristic of such a sensitized surface could be represented by the spectral response curve of Fig. 26. However, the total emission was not nearly so great as in the case of the cells containing sulphur vapor or organic dyes. It appeared, therefore, that the presence of water vapor in small quantities may have been advantageous, but was certainly not alone responsible for the whole of the observed increase in the photoelectric effect.

Perhaps the water vapor present with some such dielectric as sulphur was taken up as water of crystallization as alkali metal sulphides or sulphates were formed on the cathode surface. It is rather significant in this respect that the oxides, sulphides and sulphates of sodium and potassium quite generally hydrate if water is present, and the appearance of these hydrated crystalline forms resemble those of the photoelectric cell cathodes prepared as described earlier in this paper.¹⁷ This indicates that the surface films may have a definite configuration and the molecules a regular alignment, which really would be expected, for polar compounds in general are favorable to association, and this, as Gerlach¹⁸ commented, is a "preliminary stage of microcrystalline character." It is a well-known observation that while water of crystallization plays a definite role in the crystal structure, it reacts toward radiant energy as water vapor in its free liquid state.¹⁹

In connection with these remarks on water of crystallization, attention is called to the studies of Predwoditilew and Blinow²⁰ concerning the photoelectric emission of finely powdered crystalline sulphates. They announced a simple relation between the photoelectric current and the water of crystallization.

It occurred to us that the dielectric substance may form a surface film which reduces the work function; the molecules may well have been so aligned as to act as tiny grids setting up powerful fields which aided in pulling electrons from the alkali metals surface. This idea has been effectively

used in interpreting long wave shifts, such as are caused by oxide coatings on filaments of thermionic tubes;²¹ but we do not see how it could explain the new selective maximum appearing simultaneously with the shift.

Richardson and Young²² had a theory that the two peaks in their spectral response curves for potassium treated with water vapor and flashed in hydrogen were due to the presence of multiple thresholds on a spotted cathode; but there is nothing in their discussion to explain why the selective maxima occur at the same wave-length for all dielectrics on a given metal; unless, of course, water vapor be the activating agent in them and act independently of and more effectively than any other substances with which it might be mixed.

2. *Lack of correlation between selective maxima and absorption bands in the visible.* We found no relation between the absorbing power of the various dielectrics for *visible* light and the sensitization which they brought about, although this conclusion might be modified if the actual absorption of the deposited films of these substances could be observed. As an example of this might be mentioned the case of water vapor with its weak absorption in the visible, producing better results than cyanine at the particular wave-lengths where this dye has powerful selective absorption (4500–6500A).²³

H. THEORETICAL CONSIDERATIONS

1. *Correlation of separation of maxima with infrared vibration-rotation spectra of the dielectrics.* The absorption of light by water vapor increases in the

Fig. 30. Absorption spectra of thin films of water. Reproduced from Bull. Bur. Stand. 7, 4, 631.¹⁹

direction of increasing wave-length, and is very strong in the near infrared. It consists of a series of lines or narrow bands so related that if the frequencies of the powerful absorption bands near 6μ and 3μ be taken as fundamentals, other bands can be regarded as the first, second, and third harmonics of

²¹ J. A. Becker, Phys. Rev. 28, 341 (1926).

²² O. W. Richardson and A. F. A. Young, Roy. Soc. Proc. A107; 377 (1925).

²³ Bull. Bur. Standards No. 422 (1922).

these.²⁴ Also these frequencies seem to combine or add up to give other spectral lines. In general, frequencies corresponding to wave-lengths less than 1.5μ are not so strong (Fig. 30), but in the form of vapor or water of crystallization²⁵ the higher harmonics become sharper and more pronounced (Fig. 31), a line at 1.119μ being almost as strong as the 1.47μ line into which the 1.5μ band resolves itself. This absorption series, the "vibration-rotation

Fig. 31. Bolographic energy curves of the solar spectrum of a 60° glass prism, the upper one taken in February when the humidity was low and the lower one in September when the humidity was high. Curves reproduced after Coblentz from Fowle: *Smithsonian Misc. Coll.* Vol. 47, No. 1468, (1904).

spectrum," is due to interatomic vibrations within the molecule, or more specifically to vibrations set up between the hydrogen and oxygen atomic nuclei.

Now there seems to be considerable evidence that the increased photoelectric response is in some way, directly or indirectly, connected with this or a similar spectrum. For, in the first place, such absorption bands are quite characteristic of all compounds containing an oxygen-hydrogen carbon-hydrogen or nitrogen-hydrogen linkage, as shown in Table III.

TABLE III.

O-H Linkage ²⁶	C-H Linkage ²⁷	N-H Linkage ²⁷
3.06μ	3.28μ	2.90μ
1.469	1.68	1.50
1.119	1.145	1.03
.933	.874	.790
.718	.713	.648

There are other important bands of longer wave-length than 3μ , the ones near 6μ being particularly strong. However, (as pointed out by Ellis in discussing the bands listed here for the N-H linkage), the ones just tabulated

²⁴ H. A. Rowland, *Astrophys. J.* 6, (1897).

^{25,26} W. W. Coblentz, reference 19.

²⁷ J. W. Ellis, *Phys. Rev.* 33, 27 (1929), *Frank. Inst. J.* 208, 4, 507 (1929).

are of particular interest, for the positions of the bands are seemingly independent of the presence or nature of the solvent.

Since a band-system of the foregoing type is found in the spectra of so many different compounds involving hydrogen, it is reasonable to suppose that the vibrations to which such bands are due, occur in the molecules formed by the vapors which we brought into contact with alkali-metal surfaces.

Now we have observed a very interesting pair of numerical agreements, which are probably more than mere coincidences. On evaluating the shift in frequency δ of the long wave limit and the selective maximum, which occurs when an alkali metal is affected by one of the vapors in question, we found:

(a) In many cases this frequency-shift is equal to the frequency corresponding to the wave-length 1.5μ , which is that of a strong band in many molecules of the stated kind;

(b) In certain other cases, notably where sodium surfaces were involved, the frequency-shift is equal to the frequency corresponding to some wave-length near 1μ , where there are other bands.

A couple of other things suggest that the presence of hydrogen may be essential to these shifts: viz. Wiedmann's²⁸ data which suggested to him that not only the shifts but the actual maxima themselves are due to hydrogen; and the fact that CCl_4 contains no hydrogen, has no absorption-bands in the near infrared (Abney and Festing²⁹) and did not produce a frequency-shift, whereas CHCl_3 , with its hydrogen-content and its vibration-bands, did produce one.

We make, then, the tentative hypothesis that the frequency-shifts are due to the presence of molecules having natural vibration-frequencies equal to these shifts; and attempt to explain why such molecules should have that particular effect.

It may be that when an alkali-metal atom is incorporated into a molecule having an O-H bond (for example) the resulting complex molecule possesses a natural frequency equal to that of the alkali-metal, diminished by that appropriate to the O-H bond. It is well known that two electrical or two mechanical systems with natural frequencies of their own may be coupled into compound systems having a frequency which is the difference of theirs (cf. for instance Hartley and Peterson)³⁰. Something of the sort may occur here.

The newly-discovered phenomenon of the "Raman shift," however, offered a very tempting explanation.

2. *The Raman shift as an explanation of the frequency-shift of the spectral response curves.* In the language of the quantum-theory of light, a "Raman shift"³¹ occurs when a quantum or photon collides with a molecule, causes

²⁸ G. Wiedmann, reference 8.

the molecule to pass from its initial to another of its stationary states, receives the energy which the molecule gives up (or alternatively, gives up the energy which the molecules absorb) in making this transition, and flies off with energy correspondingly increased (or diminished). In the language of the wave-theory (Hartley³²) a Raman shift occurs when the frequency p of an incident wave-train of light is modulated by the frequency q of a natural vibration of the molecule on which the light falls, the shifted wave-trains being the "sidebands" of frequencies $p+q$, $p-q$, $2p-q$, etc.

Now suppose that some of the quanta striking the treated alkali-metal surface collide with molecules which are not in the normal, but in some excited state of vibration; and that in such a case, the molecule transfers to the quantum the amount of energy which it would release in the form of radiation, if it were spontaneously to relapse to a lower vibration-state; for instance, that it transfers the energy of one quantum of radiation of wave-length 1.5μ . Then the quanta which have made such collisions have their frequencies correspondingly augmented. If now they fall on the alkali metal and produce the photoeffect, it is the photoeffect proper to light of augmented frequency which they produce. The spectral-response curve would then be shifted because the frequency of the light itself is shifted before it reaches the photo-sensitive surface.

This idea was temporarily adopted as a working hypothesis; but a number of objections arose which are hard to surmount. In the first place, the sense of the shift is such that we must suppose the quanta to collide with molecules already excited. Now in a substance in thermal equilibrium, the proportion of molecules in any given state of excitation may be computed by Boltzmann's equation:

$$n = n_0 e^{(-\epsilon/kT)} \quad (1)$$

in which T stands for the temperature of the substance, k for the Boltzmann constant, n_0 for the number of molecules in the normal state or state of least energy, and ϵ for the energy of the given excited state referred to that of the normal state as zero. It seems unlikely that the proportion of excited molecules should be great enough to account for such results as those shown in Fig. 14 (for example) or in Fig. 32, where the "shifted" is as large as the regular maximum,—a result obtained when very thin films of potassium were flashed in hydrogen on oxidized copper plates. And it seemed doubly unlikely that the excited molecules should be numerous enough to explain the presence of such pronounced maxima at long wave-lengths as those shown in Fig. 7, where in the cases of curves (a) and (b) they are several times the magnitude of the regular maximum for caesium at $\lambda 5500\text{\AA}$.

One would expect encounters in which quanta give energy to normal molecules to be far more abundant than encounters in which quanta receive energy from excited molecules. In other words, if p stands for the frequency of the incident light and q for that of the vibrating molecule, the $p-q$ frequency should be more intense than the $p+q$ frequency and possibly present

³² R. V. L. Hartley, reference 30.

when the latter was not. There should then, be a new maximum, much stronger than the one which we have observed, located towards higher

Fig. 32. Spectral response curve for a potassium film flashed in hydrogen on a copper-oxide plate

frequencies from the maximum characteristic of the pure metal. We were not fully equipped to investigate this region and so obtained no definite

Fig. 33. Spectral response curves showing how Richardson's and Compton's observed double maxima for a sodium photoelectric cell appear as the regular selective maximum of Pohl and Pringsheim plus this maximum shifted to higher frequencies by an amount corresponding to the frequency of the $\lambda 0.718\mu$ water vapor absorption line.

information. However, the curves for caesium cells (Fig. 7) show evidence of a maximum at higher frequencies, and also the shift of the $\lambda 4360$ peak of

pure potassium to somewhat higher frequencies (Fig. 5) upon treatment with dielectrics might be explained by assuming the $p-q$ frequencies greater than the $p+q$ and taking q equal to the frequency of the intense 3μ water vapor band. Richardson and Compton have published a curve for sodium showing a peak at $\lambda 2270\text{\AA}$ in addition to the regular one at $\lambda 3600\text{\AA}$. Since the cell they used had electrodes sealed in with cement which would prevent thorough baking, water vapor was probably present. The ultraviolet peak could be explained as a $p-q$ frequency if we put q for the frequency of the 0.718μ line of the vibration-rotation spectrum of water vapor. In Fig. 33 is plotted a curve based on the assumption that this $p-q$ frequency produces

Fig. 34. Theoretical modifications of the spectral response curve for potassium photoelectric cells, assuming modulation of the incident light frequency p by the strong 3μ absorption band of water vapor. a) Curve for pure potassium (Pohl and Pringsheim). b) Curve (a) shifted to higher frequencies by an amount corresponding to $q=c/3\mu$ to show the effect of the $p-q$ side frequencies. c) Curve (a) shifted to lower frequencies by a similar amount to show the effect of the $p+q$ side frequencies. d) Composite curves assuming the presence of the incident light frequency p and the side frequencies $p \pm q$, illustrating the shift of the maximum to shorter wave-lengths with a decrease in the intensity of the $p+q$ sideband.

a maximum as strong as the unmodulated p frequency,—an assumption probably false. The shift of the long wave limit might also be taken to indicate the presence of a weak positive side frequency, also.

In Figs. 34 and 35 are plotted some theoretical curves for potassium cathodes, assuming the $p \pm q$ frequencies to be operative with varying intensities. In Fig. 36 is illustrated the close agreement between the theoretical and observed values. Similar curves for sodium may be shown.

We might avoid the need for postulating a transfer of energy to quanta from excited molecules by assuming that two quanta simultaneously strike a normal molecule and excite it, and a single quantum is then radiated having energy equal to the sum of their energies less that required to excite the mole-

cule. This seems a highly improbable event; but in any case the experiments which we are now about to describe exclude it, for if the theory were correct

the kinetic energy of the emerging electrons would be equal to $2h\nu$ minus the surface work function, instead of to $h\nu$ minus this function.

However, the gravest objection to the "Raman Shift" theory is that it requires that the electrons should receive the energy $h(\nu + \delta)$ rather than the energy $h\nu$ when the substance is illuminated by light of frequency ν ; so that the adverse voltage as read on the voltmeter which is required to stop the fastest electrons, the "apparent stopping potential," should be increased by the amount corresponding to $h\delta$ when the vapor is admitted to the metal. No such effect has ever been observed; but as the interpretation of the data requires an allowance for contact potential, this point must be left for discussion in the next section.

3. *Accurate determination of the stopping-potential vs. frequency curve and evaluation of h .* According to the well-known Einstein equation

$$Ve = \frac{1}{2}mv^2 = h(\nu - \nu_0) \quad (2)$$

the graph of stopping potential versus frequency should be a straight line of slope h . Our experiments have verified this prediction over a range of frequencies heretofore unemployed and extending into the infrared, have led to a very precise value of h , and have incidentally eliminated the idea mentioned above that a frequency $(2p - q)$ might result from the interaction of light with the molecules; for that idea would require a slope equal to $2h$.

A photoelectric cell was specially designed to avoid the deposition of photosensitive materials on the anode, for this is fatal to accurate determinations of stopping potentials as will be explained directly. As will be seen from Fig. 37, the cathode could be coated with freshly distilled sodium in one end of the tube and then transferred in vacuum to the other end where it became a central cathode surrounded by a cylindrical anode made of soot-coated nickel. Again at any time the cathode could be removed to its original position for further sensitization.

The potential drop across the electrodes of such a cell read on the voltmeter is of course not the true one; allowance must be made for contact difference of potential. The voltage at which the current just saturates would be that for the true potential drop equal to zero, if the anode completely encompassed the cathode. When there are small openings in the anode, such as a hole through which to introduce the exciting light, a slight positive potential is required to produce saturation of the photoelectric current. It is always possible, however, to find the effective or true zero voltage if the long wave limit is carefully determined, as will soon be shown. The true stopping-potential is then measured by the distance, along the axis of voltage, from that point to the point where the current just reaches zero. This last would not be true if the cylinder emitted electrons, for then there would be a "reverse" current when the field was so directed as to drive electrons from it to the central electrode, and the net current would vanish when this just balanced the direct current, not when the direct current itself vanished. But in our experiments the cylinder was not photosensitive at all, and there were never any reverse currents.

The photoelectric currents were measured by means of a Compton quadrant electrometer, using the constant deflection method. The cathode

was illuminated sometimes by the highly resolved light of a glowing tungsten filament, sometimes by means of the monochromatic lines of the quartz mercury arc. The arc lines used were isolated by passing the light through a Hilger quartz monochromator and using an Eastman filter which cut out all stray light of higher frequencies. The great amount of long wave-length

Fig. 37. Specially designed photoelectric cell for the study of stopping potentials. *A*—Tubular connection to evacuating system and entrance for sodium. *B*—Tube leading to side arm containing sulphur. *C*—Cathode of cell on which sodium is deposited. *D*—Phosphor bronze ribbon connecting cathode with external electrode. *E*—Glass stem supporting cathode while it is coated and sensitized and in which CO_2 snow was packed. *F*—Electrode forming electrical contact with coating of sodium used as temporary anode. *G*—Tube down which the sensitized cathode slides after it is sensitized and in which was kept a heating coil during the coating process. *H*—Insensitive anode to which the electrons were emitted after the tube was made.

energy radiated from a glowing tungsten filament made it easily possible to measure stopping potentials for light of wave-lengths up to 8000\AA with surfaces sensitized by means of dielectrics. This light was passed through a monochromator and a light filter cutting out higher frequencies, and the stopping potentials determined. Corrections for slit width were made before plotting the results. The stopping potentials were then redetermined using a

monochromator of different dispersion. The results obtained with the different instruments checked perfectly.

Both for pure sodium and sodium treated with sulphur vapor and air the curves obtained were straight lines of slope h , as shown in Fig. 38. The value of h obtained from the pure sodium cannot be considered so accurate as that obtained from the sensitized sodium surface because of the few points on the curve and the narrow spectral band to which they are confined. However, even the value $h = 6.6 \times 10^{-27}$ can be considered a fair check of this important constant.

The curve taken after sensitizing the sodium as described earlier in this paper was very carefully determined with wave-lengths of light varying from 3500\AA to 8000\AA , and, the value of h ($= 6.541 \times 10^{-27}$) can be considered

Fig. 38. Stopping potentials versus light frequencies for a sodium cathode before and after sensitizing it with sulphur and air treatments. The spectral response curves for both conditions are shown in the insets.

accurate to at least three significant figures. Perhaps this is the first time that stopping potentials for light of wave-lengths longer than $\lambda 5461\text{\AA}$ have been used in the determination of the value of h .

We never observed any line of slope $2h$. This excludes the idea of a transfer of energy to a normal molecule from two exciting quanta.

When we plot true stopping potentials (measured in the manner just described) against light frequency for pure sodium and treated sodium as is done in Fig. 38, we obtain two parallel lines displaced from one another by the frequency shift δ corresponding to 1.47μ which has already been emphasized. When we plot *apparent stopping potentials* as read by the voltmeter, the two lines fall on one another (Fig. 39). This signifies that the surface work-function of the treated surface has been diminished and the contact potential

increased by the amount corresponding in volts to δ . The electrons initially received the energy $h\nu$ from the quanta, but lose less of it in getting out through the surface, so that in effect their kinetic energy after escape is greater by $h\delta$ than it was with the pure sodium. By the Raman shift theory their kinetic energy would also have been greater by $h\delta$ after the treatment of the surface; but then the surface work function and the contact potential would have remained the same, and the apparent stopping potentials would have been shifted by δ .

To put the foregoing statements into algebraic form we may write the V of equation (2) as the sum of the P.D. registered by the voltmeter, say V_0 , and the contact potential difference K :

$$(V_0 + K)e = h(\nu - \nu_0) = \frac{1}{2}mv^2. \quad (3)$$

Now, it is generally agreed by all investigators that when the anode is preserved unchanged, and different surfaces are used as cathodes, the stopping potential for a given wave-length of light is the same for all. Therefore, if we use primes to denote the values of V_0 and K for treated as distinguished from untreated sodium, we have,

$$(V_0' + K') - (V_0 + K) = h/e(\nu_0 - \nu_0'). \quad (4)$$

If the light frequency remains unchanged, $V_0' - V_0 = 0$, and

$$K' - K = h/e(\nu_0 - \nu_0'). \quad (5)$$

If, however, the incident light frequency is modulated, and the surface work function remains unchanged, $V_0' - V_0$ would not be zero and Eq. (7) would not explain the facts. Here was a criterion for deciding whether or not the light was modulated.

The stopping potential curves shown in Fig. 39 all refer to the same cell, one of the type shown in Fig. 37. It will be seen that the apparent stopping potentials for a given wave-length of incident light are the same before introduction of the dielectric as after.³³ The increased velocity of emission of the electrons after treatment with sulphur and air was due to a reduction of the work-function of approximately 0.8 volt which was the contact difference of potential between pure sodium and the sodium treated with the dielectric. For this particular case, then, Einstein's equation might be extended to read:

$$K' - K = \frac{h}{e}(\nu_0 - \nu_0') = \frac{h}{e} \frac{c}{1.47\mu}. \quad (6)$$

Here is ample evidence that the light frequencies incident on the surface are not modulated.

Referring again to Fig. 39 attention is called to the way in which all plots of the light frequency versus apparent stopping-potentials, (voltages

³³ Actually, the cathode voltage at which the current became zero was 0.5 volt more positive before admitting the dielectric than after, but this was due to the fact that the sulphur vapor and air which entered the cell had made the anode more electronegative as well as the cathode more electropositive.

at which no electrons reach the anode) fall on the same straight line which intersects the effective zero voltages at frequencies corresponding to the long wave limits of the respective cathodes. Failure of the voltage-current curves to break exactly at the effective zero is due to the fact that the anode did not enclose the cathode completely as explained above. A slight positive voltage had to be supplied to the anode before it gathered all of the emitted electrons. However, the separation of the voltages at which the currents saturate, designated by (b) and (d) and the separation of the effective zeros (a) and (c) are practically identical, and the relationship between the

that contact difference of potential was a property not alone of surfaces but of molecules and, as such, a measure of the relative number of available valence electrons under excitation of light, or the relative ease with which these loosely bound electrons can be liberated by light.

I. GENERALIZATION OF THE LINDEMANN FORMULA

In 1911 F. A. Lindemann³⁴ derived, from each of two very simple models, the following formula for a natural frequency ν which he proceeded to identify with the frequency of the selective photoelectric maximum:

$$2\pi\nu = (ne^2/mr^3)^{1/2} \quad (e, m \text{ charge and mass of electron}). \quad (7)$$

This is the frequency of an electron revolving in a circular orbit of radius r (or an elliptical orbit of major axis r) about a stationary charge of magnitude $+ne$. It is also the natural frequency of vibration of a system composed of two interpenetrating spheres of continuously-distributed positive and negative charge, having radii r , and total charges $\pm ne$ and $\pm e$ respectively.

Putting n equal to unity, and putting for r the radii of the atoms of the various alkali metals (obtained from their atomic volumes in the solid state) Lindemann obtained numerical values very close to the frequencies of the chief selective maxima of these metals as then known and subsequently checked (Pohl and Pringsheim, Braun,³⁵ Seiler,³⁶ and others). See Fig. 29. His values and the experimental ones, converted into wave-lengths, are shown in Table IV.

TABLE IV. *Specific wave-length of selective photoelectric effect.*

Metal	By Lindemann Formula	Observed
Cs	5500	5100
Rb	4900	4800
K	4380	4350
Na	3180	3400
Li	2360	2800

Subsequently Gross³⁷ showed that additional maxima observed by some workers for certain of the alkali metals fall at frequencies ν agreeing well with the formula

$$2\pi\nu = (ne^2/mr^3)^{1/2}$$

provided proper integer values be assigned to n .

Some of these agreements are so noteworthy, that it seems worth while to use the Lindemann model, primitive though it may appear in the light of recent theory. Now the choice of the value unity for n , which Lindemann

³⁴ F. A. Lindemann Verh. d. D. Phys. Ges. 13, 482 (1911). Verh. d. D. Phys. Ges. 13, 1107 (1911).

³⁵ Braun, "Die Photoelektrischen Wirkungen der Alkali Metalle in Homogenen Licht," Boun 1906.

³⁶ E. F. Seiler, reference 5.

³⁷ F. Gross, reference 3.

made, corresponds to an electron revolving around a singly-charged ion—the sort of ion one would expect from a monovalent substance, such as the alkali metals are. Such values as 2, 3, . . . for n would correspond to an electron revolving around a doubly-, triply-, . . . charged ion, such as a di-, tri- . . . valent substance would have. We might then say that in some atom-groups the alkali metals are divalent or trivalent, and that these are responsible for the maxima of higher frequencies which Gross considered.

Now in our experiments, we have checked several of the maxima to which the original Lindemann formula and the formula with Gross' modifications apply; and we have also observed maxima of lower frequency—those to which this paper is chiefly devoted—many of which are located at frequencies given by the Lindemann formula, provided that simple fractional values are assigned to the factor n .

Continuing with the model, we might say that such values of n are associated with atoms of valency $\frac{2}{3}$, $\frac{1}{2}$, and the like. To think of an electron revolving around an ion with net charge $+2e/3$ seems strange at first; but it is quite conceivable that the forces exerted on the electron by the other surrounding atoms might have the same net effect. We propose therefore to designate even the fractional values of n as "valencies".^{37a}

Our data, together with those of the observers already quoted, are listed in Tables V, VI and VII, being classified according to the metals involved. The second column of each table gives the various values assigned to n ; the third the corresponding wave-lengths, derived from the frequency computed by the generalized Lindemann formula; the fourth, the wave-lengths of the observed maxima; the fifth, the authorities. In the first column, we give the formulae for oxides in which the metal in question displays these valencies.

Now it is an important fact that most of these oxides are known to exist.³⁸

TABLE V. *Lindemann formula* $\nu_{\max} = (1/2\pi)(ne^2/mr^3)^{1/2}$.

the oxides of sodium are listed Na_4O , Na_3O ,³⁹ Na_2O and Na_2O_2 , showing valencies for sodium ranging from 0.5 to 2. Since the likely presence of traces of water vapor in all the dielectrics introduced onto the alkali metals has been admitted and since atmospheric air was admitted in some cases,

it may well be that some oxide is formed on the cathode surface; and this may have been a suboxide. (The formation of the higher oxides should result in increasing the response to shorter wave-lengths.) As evidence that it actually was a suboxide, I cite experiments which showed that the cells

were red-sensitive only when very small amounts of the dielectrics were used. If a certain critical amount was exceeded the response to red decreased greatly, and soon entirely disappeared. If, however at this stage a point

³⁹ R. de Foicrand, *Compt. Rend.* 127, 364, 514 (1898).

near the cell window was heated, a vapor of sodium plus some of the dielectric was created in the cell. This lent itself to the formation of a subvalent compound on the surface and the characteristic response to light of long wavelengths was again in evidence. Moreover, the general appearance of the cathode of sodium cells so treated was exactly that of sodium suboxide, viz. a grey, porous surface crust.

Suboxides of potassium⁴⁰ and caesium⁴¹ are also known, but they are more difficult to prepare and apparently are only obtained by limiting the amount of oxygen first coming in contact with the metal. Really this is to be expected for it is impossible to prepare oxygen sufficiently dry that it will not react with either potassium or caesium, but sodium can be distilled in dry oxygen without reaction. In the case of caesium, the suboxides are only formed by limiting the amount of oxygen present and holding the temperature at a certain value. Naturally, then, it would be expected that sodium-suboxide photoelectric cells could be made with less difficulty than potassium or caesium suboxide cells. However, by flashing hydrogen on thin potassium films deposited on oxidized copper plates in vacuum, very much as Campbell⁴² has reported, a compound which apparently was potassium suboxide, was prepared. Also by proper control of the temperature, as caesium vapor came in contact with an oxidized silver plate in vacuum, caesium suboxide was formed. Each of these compounds produced a new and pronounced maximum in the spectral response curves, the former at 6200A and the latter at about 7700A. (See Figs. 32 and 7.)

There is no reason to assume, however, that such subvalent compounds are limited to the oxides. The main and limiting requirement for red sensitivity is undoubtedly the subvalent condition of the atoms in the molecules, and possibly these may be subhalides, subsulphides, or some other subvalent salts. However, not many such compounds are known; and water vapor was in all probability always present in the small amounts likely to form suboxides. The broadening of these maxima in cases when certain dyes or dielectrics were used (Figs. 12, 25) was probably due to intense absorption of these complex compounds on the long wave side of this maximum.

The work of Dima⁴³ on the oxides of manganese and various compounds of other metals suggests a similar theory; for using unresolved light, he found that the lower the valency of the metal in the compounds, the more photo-sensitive the compound. This may have been due to the shift of the maximum towards the red.

It is practically impossible to prepare a suboxide of a metal without at the same time forming some higher oxides as well. These should correspond to integer values of n in Lindemann's formula; and maxima explainable in this way have actually been observed. As in the case of the maximum for $n = 1$

⁴⁰ J. J. Berzelius, *Lehrbuch der Chemie*, Dresden 1, 749 (1825).

shown by multiply distilled sodium, the additional maxima for treated sodium surfaces also generally fall at slightly greater wave-lengths than the computed values, (Table V). However, the second selective maximum observed in the ultraviolet by Richardson and Compton for sodium fits closely the maximum to be expected if $n=2$, the valence of Na in Na_2O_2 . The shift of the long wave limit to greater values suggests the presence of the suboxide ($n=0.5$) in small quantities. Since their experimental conditions precluded the possibility of thoroughly eliminating moisture from the glass walls, the likelihood of these compounds being present must be admitted.

The last three oxides listed in the potassium group (Table VI) may have been responsible for the apparent shift of the regular selective maximum for that metal to shorter wave-lengths as quite generally observed after treatment with the dielectrics, (Figs. 5, 23). Moreover, for $n=2$ (the valence of K in K_2O_2) Lindemann's formula gives a maximum at almost exactly the same wave-length as that attributed to oxygen on potassium by Wiedmann.

The difficulties in preparing pure, silvery caesium in bulk form may explain why most investigators seeking to establish the presence of a selective maximum at $\lambda 5500\text{\AA}$ ($n=1$ in the Lindemann formula) for caesium, found a greater peak in the ultraviolet. For, even after multiply distilling caesium in vacuum, it usually appears slightly golden in color as if containing some oxides. If the valence of Cs in these oxides is greater than unity ($n>1$) the selective maxima should fall in the ultraviolet, as observed. As a matter of fact, experiments show that by introducing caesium onto an oxidized plate under proper temperature conditions, the regular selective maximum ($n=1$) can be made to disappear almost entirely, as shown in Fig. 7, indicating that practically all free caesium had disappeared. At the same time the maxima due to the suboxides ($n<1$) and peroxides ($n>1$) become very pronounced.

In the foregoing computations the value of the atomic radius r was left unchanged as n was modified. The alkali metal atom in the molecule was considered as an isolated atom of normal dimensions but with a different force-constant.

J. COMPARISON OF AFORE-MENTIONED HYPOTHESES

Two seemingly different and unrelated theories have been advanced to explain the displaced selective maximum. In the first one it was assumed that there is hydrogen present, a condition not unlikely since sodium and potassium absorb great quantities of this gas without any change in their metallic appearance, much as does palladium.⁴⁴ It is further assumed that addition of some such dielectric as oxygen or nitrogen results in the appearance of characteristic vibration-rotation frequencies which were apparently subtracted from the resonance frequency of the electron in the alkali metal atom. The other theory is based on the Lindemann equation, and accounts for the reduced resonance frequency as a consequence of a decreased binding

⁴⁴ P. Hautefeuille and L. Troost, *Ann. Chem. Phys.* (5), 2, 273 (1874), *Compt. Rend.* 78, 809 (1874).

force on the electron correlated with a change in the valence of the alkali metals in the molecules of the compound formed on the cathode, the atoms in a subvalent condition responding to light of longer wave-lengths.

Until more is known concerning valence and molecular structure, attempts to correlate the two theories would be outright conjecture. It may be that the reason the two theories appear to explain the same phenomena is that they are both built around similar structures. For example, the very unusual molecule Na_4O may be structurally written (for want of a better formula)

On the other hand, if hydrogen is assumed present with the alkali metals the introduction of oxygen (say) into a photoelectric cell and subsequent treatment, as described above, might result in the formation of molecules which may be written:

In this connection, it is significant that dry oxygen will not react with sodium. Now, the valence of the sodium atom in each of these compounds is identical, and yet the latter is shown to contain the atoms giving rise to the spectrum of water vapor. The valence of the sodium atoms being similarly reduced in each case, the resonance frequency of the valence electron would be correspondingly decreased and the response to long wave light increased.

Either theory may be made to account for the observation that for small ratios of oxygen atoms (say) to alkali metal atoms in a molecule, the response to red light becomes greater. This would be expected by the first theory, for when the atoms are attenuated, higher vibration-rotation frequencies become sharper, as pointed out previously for the case of water of crystallization.⁴⁵ It would also be expected by the second theory, for the valence of the metal and consequently the binding force on the electron would correspondingly be lessened.

K. IRREGULARITIES IN VOLTAGE-CURRENT CURVES EXPLAINED

The fact that higher voltages are required to bring about current-saturation when the surfaces are irradiated with light of large wave-lengths can be easily explained by a comparison of the contact potentials of the materials comprising the cathodes of red-sensitive cells. Experiment showed (Fig. 39) that the complex surface formed when the dielectrics were introduced onto an alkali metal cathode was electropositive with respect to the metal by as much as 0.8 volt, and since, within distances comparable to molecular diameters, both free atoms and these complex molecules were existing on the surface, electrons released from the molecules by long wave light would

⁴⁵ W. W. Coblenz, reference 19.

encounter strong opposing fields and their escape would be impeded. They would be pulled to the anode only when sufficient voltage was applied to offset these local surface fields. On the other hand, electrons released by light of shorter wave-lengths come primarily from the free atoms and since these are electronegative with respect to the molecules on the surface, the electrons encounter a helping rather than an impeding force. Consequently, the photoelectric current will saturate at lower voltages for blue light than for red light.

The phenomena, shown in Figs. 2, 3 and 28 and which might be called supersaturation, may be explained by the shape of the elements of the tube. To understand better why more electrons should reach the anode at low voltages than at high, the history of the cell will be reviewed. The first step after evacuation of the bulb was the coating of the entire inner walls with potassium or sodium. Next, by applying a fine point flame momentarily on the face of the bulb, the metal was caused to recede and form an opening through which light could enter the cell. But without thorough heating, the glass could not be made perfectly non-conducting; and on account of the

Fig. 40. Diagrams indicating the geometry of the electric fields within photoelectric cells having closed ring anodes (a) before treatment with dielectrics and (b) after such treatment.

low melting points of the alkali metals, prolonged heating of the "window" would have ruined the entire coating of the cell. Even if it were temporarily cleaned of all potassium, the high vapor pressure of the alkali metal produced by the heat of the flame would have deposited metal enough on the window to make it conducting afterward.

Now, the general shape of the electric field set up by an applied polarizing voltage within such a cell might be represented by the direction lines of diagram (a) Fig. 40. It is at once evident that the effect of increasing the polarizing voltage would be that of increasing the number of electrons reaching the anode up to complete saturation. This would result in a normal voltage-current relation. When, however, the conducting film on the glass window was destroyed by some active gas or dielectric, or by repeated heating afterward, the shape of the polarizing field changed to that illustrated by the directional lines of diagram (b). In effect the field between the window and the closed ring or anode was wiped out. From the point C the field spread radially toward the plane of ring A. For such a field there is a critical voltage at which the greatest number of emitted electrons arrive at a collector

located at some angle to the normal from an illuminated spot. These voltages have been computed for a similar case and published by Fry and Ives⁴⁶ and their computations experimentally verified by Ives, Olpin and Johnsrud⁴⁷ for central cathode photoelectric cells. The striking similarity of their curves and the voltage-current curves shown in Fig. 28, for illumination at back and side of cells treated with dielectrics, is illustrated in Fig. 41. It might also be that the greater energies of emission after treatment with the dielectric tended to augment this condition.

Apparently then, the closed ring used for the anode of these cells was responsible for these peculiarities in the voltage-current relation. Data

Fig. 41. Comparison of voltage-current curves obtained with photoelectric cells having closed ring electrodes as shown in Fig. 40(b) and voltage-current curves observed with anodes fixed at given angles to the normal to the cathode for cells having radial fields, as described by Ives, Olpin and Johnsrud.⁴⁷ a—Curve 4 of Fig. 28. Light incident at C (Fig. 40) b—Curve for a cell with a radial field when the collecting segment was located at 10° to the normal from the cathode. c—Curve 6 of Fig. 28. Light incident at B (Fig. 40). d—Curve for a cell with radial field when the collecting segment was located at 10° to the normal from the cathode.

obtained from cells having different shaped anodes, such as straight wires or grids, failed to show these peaks at low voltages. Finally a cell was made having a closed ring anode which could be rotated and set with its plane perpendicular to or parallel to the illuminated spot on the cell wall. Whenever, the plane of the ring was parallel to the back of the cell on which the light was falling, the peaks at low voltages appeared and whenever the ring was turned through 90° these maxima disappeared.

L. CONSIDERATIONS IN THE REALM OF PHOTOGRAPHY FLUORESCENCE AND LIGHT ABSORPTION

While there is not space for more extensive discussions, it seems important to call attention to apparently analogous phenomena in the fields of photography, light absorption and fluorescence. It certainly seems more than a coincidence that photographic plates and photoelectric cells can be sensitized to red and infrared light by such strikingly similar methods. The presence of traces of sulphur in the gelatines obtained from some sources has been given by investigators at the Eastman Research Laboratories⁴⁸ as an explanation for their high sensitivity to light. Certainly these experiments, together with those wherein photographic plates are sensitized to red and infrared light by means of organic dyes, suggest a close relationship between photographic and photoelectric phenomena.

Saha⁴⁹ and others have already advanced theories in which fluorescence with change of wave-length is attributed to modulation of the exciting light. In general, however, his conclusions have not been enthusiastically received, many unexplainable observations standing in the way of such a theory. Certainly, however, it should not be dismissed without further consideration. Such results as Wood and Kinsey⁵⁰ reported wherein the *D* lines of sodium were excited by radiation in the region of 5100–5250Å when the sodium vapor was mixed with low pressures of hydrogen, nitrogen or air, seem significant, indeed, since the wave-length region of the exciting radiation here coincides with that of the new photoelectric maximum in the spectral response curves for sodium cathodes treated with air, and the photoelectric threshold for pure sodium atoms coincides with the *D* lines.⁵¹

Many other closely analogous phenomena might be mentioned here; such, for instance, as the fact that the absorption lines of an absorbing medium are noticeably shifted to longer wave-lengths when the absorbing medium is dissolved in a dielectric.⁵² But these are beyond the scope of this paper.

ACKNOWLEDGMENT

To Mr. G. R. Stilwell for invaluable contributions to the technique and art involved in the manufacture of the cells described above, to Dr. Herbert E. Ives for careful consideration of problems encountered in this investigation and for helpful suggestions, and to Dr. K. K. Darrow and Dr. Homer H. Lowry for constructive study of this manuscript, the author expresses his heartiest appreciation.

THE INFRARED ABSORPTION OF SOME ORGANIC LIQUIDS UNDER HIGH RESOLUTION

PART II

BY R. BOWLING BARNES

JOHN HOPKINS UNIVERSITY, BALTIMORE, MARYLAND

(Received June 9, 1930)

ABSTRACT

The study of the C-H vibrations bands, which occur in organic liquids between 3.0μ and 4.0μ , has been continued and extended. A more powerful spectrometer, with which wave-lengths can be determined as accurately as $\pm 0.001\mu$, has been developed for this work. Values are given here for water-vapor, benzene and toluene.

IN A recent paper,¹ we gave an account of an attempt to obtain very accurate values for the C-H absorption bands of various organic liquids. In this discussion we stated the wave-lengths of benzene and eight of its derivatives with an estimated accuracy of $\pm 0.003\mu$. This present paper is intended primarily to outline the developments in the construction of the spectrometer, and the improvements which have been made in the technique and methods. These advances enable us to state wave-lengths now as close as $\pm 0.001\mu$.

By using an echelette grating rather than a rock-salt prism, the resolving power may be increased by a factor of 10 or more. For instance, in this region of the spectrum, a 10 cm prism has a resolving power of only about 170. So, even by using four-prism dispersion, one still has a resolving power somewhat less than 1000, neglecting any loss due to the finite width of the slits. On the other hand, in the grating spectrometer described in our last paper, the theoretical resolving power was over 10,000. In this region, this puts the theoretical limit of resolution for the two types of spectrometers at 30 A'' and 3 A'' respectively, the approximation to these values being determined by the width of the slits and the perfection of the optical systems being used.

In striving to approach these theoretical limits of resolution one uses very narrow slits. When this is done however, another factor becomes of considerable importance in determining the actual limit. In a paper at the April meeting of the American Physical Society² we called attention to the effects of various aberrations in this respect.

If one is not fortunate enough to have properly parabolized mirrors, one must resort to the use of spherical mirrors "off the optic axis." As long as the numerical apertures are small, and the slits are comparatively wide, the effects of the aberrations introduced are negligible. But, if we use apertures as large

¹ R. Bowling Barnes, Phys. Rev. 35, 1524 (1930).

² R. Bowling Barnes and A. H. Pfund, Bulletin Amer. Phys. Soc. 5, 2 (1930).

as $f \cdot 4$ the effects of coma become very pronounced, and the image of the first slit is broad and is accompanied by a diffuse wing. This entire image cannot go through a narrow second slit, and consequently, if the eye is placed behind S_2 , or in the position of the thermocouple, it will receive light

Fig. 1. Grating viewed through second slit of spectrometer when illuminated with monochromatic light. Spectral line is accompanied by a wing produced by the aberrations of the optical system.

from only a very small fraction of the grating, if the latter is illuminated with monochromatic light. Patterns such as those shown in Fig. 1 may be seen, the jaws of the slit having blocked off the light coming from some parts of the grating. However, if we use continuous radiation, such as that from a

Fig. 2. Plan of spectrometer. Designed to minimize the effect of aberrations.

Nernst lamp, the spectrum falling upon S_2 will necessarily be very impure, and hence the resolving power will be correspondingly low. This diffuseness of the slit image is also a serious handicap in obtaining a very accurate calibration of the spectrometer.

The apparatus which we are using at present is a grating spectrometer, the plan of which is given in Fig. 2. It makes use of about 3.5 inches of a 3600 line per inch echelette grating, which gives it a theoretical resolving power of over 12,000. By a method analogous to that described by Pfund,³ we have been able to use $f \cdot 4$ spherical mirrors along the axis and so minimize all of these aberrations mentioned above. The radiation diverging from S_1 passes through a slot in M_4 , is collimated and returned along the axis by M_3 to the plane mirror M_4 which directs it to the grating. Similarly, the diffracted beam is reflected by M_5 to M_6 , the second spherical mirror, and this focusses upon S_2 which lies on the axis just behind M_6 , an image of S_1 that is sharp and free from aberrations. With this optical system, we have satisfied the condition that the thermocouple shall receive radiation which comes from the entire grating, when monochromatic light is used and the slits are very narrow.

CALIBRATION

A calibration more accurate than $\pm 5 \text{ A}''$, was obtained by observing the settings of the grating which would direct the various orders of the spectrum from a mercury lamp, on to the second slit. By interposing a plane mirror at 45° just behind S_2 , the transmitted light could be reflected into a microscope

Fig. 3. Calibration mirror system.

which was a permanent part of the apparatus. This microscope was focussed upon S_2 , the crosshairs set upon the center of the slit, and then the latter was opened very wide. As the grating was rotated, the spectral lines passed in turn by the cross-hairs, and an observer could thus tell accurately when the grating was set so as to send known wave-lengths through S_2 . A second observer noted the grating positions by reading on a scale 3 m distant, the image of a lamp filament that had been twice reflected by a mirror which rotated rigidly with the grating. This was accomplished in the manner shown in Fig. 3. Light from an incandescent lamp after passing through a lens was reflected by M_0 to a fixed mirror M_1 , which returned it to M_0 . After a second

³ A. H. Pfund, J.O.S.A. 14, 377 (1927).

reflection by M_0 it was sent along path 1 to the scale upon which an image of the lamp filament was formed. This double reflection causes the beam of light to swing through an arc four (4) times that through which the grating is rotated. The linear displacement of the image of the filament thus becomes large. To avoid the necessity of having a very long scale, a second fixed mirror, M_2 , was mounted as is shown. The angle between M_1 and M_2 was adjusted so that as the grating and M_0 were rotated image 2 came onto the scale just as image 1 was going off the opposite end. If the grating must be rotated through a large angle, a third mirror M_3 could be mounted in a similar manner causing a third image to follow image 2. A linear motion of the filament image of 1 mm at 3 m scale distance, represents a rotation of the grating of about 17 sec. of arc. If the beam of light is allowed to be reflected by M_0 three times, a displacement of 1mm would represent a rotation of only 8.5 seconds. If necessary, more than three reflections can easily be used, and also the image of the filament can safely be read to 0.1 mm. This gives us a method of handling with ease rotations of the order of 1 second of arc. In all of this work the image was moved in steps of 1 mm, this indicating a change in the wave-length falling upon the thermocouple slightly less than 10 \AA '. The calibration was carefully checked from time to time, and was always known closer than $\pm 5 \text{\AA}'$.

PROCEDURE

At best, the point by point method which is usually employed in making infrared measurements is a rather long and tedious process. Every step taken to improve the instruments used, in regard to sensitivity and resolving power, requires that more readings per μ be taken. Obviously, with very high resolution the problem of making such measurements becomes painfully taxing. However, we have so improved our methods that at present we can measure the absorption at over 500 different grating settings within an hour, whereas last year 50 readings constituted a full hour's work. The most fundamental step in making this possible resulted from the recent work of Dr. Pfund on controllable filters for the infrared. Since a grating superposes orders, the effect of the second order of the 1.5μ region and the third order of the 1.0μ region must be eliminated, or to say the least, must be taken into account. For this purpose, one of the MgO filters described by Dr. Pfund⁴ is admirably suited. Also, a filter of a glass designed for use in solar observations was found, which was over 60 percent transparent at 3.5μ , and only 5 percent at 1.75μ and below. These filters, it is true, did not entirely eliminate the effect of the higher orders, but did succeed in reducing it sufficiently for our purposes. For instance, the one we used, though it had a transmission of only 5 percent at 1.75μ , due to the intense emission of the Nernst filament in that region transmitted enough higher order radiation to cause a contamination of the 3.5μ energy of 30 percent. It was shown separately, however, by using 100 percent 1.75μ energy, that in such small thicknesses the

⁴ A. H. Pfund, Phys. Rev. July 15, 1930.

absorption of these higher orders was negligible. So, by using either of these filters, the desired results were obtained.

Further, it was found that by proper shielding the zero drift of the galvanometer could be held to a very small amount and so, instead of reading the zero between each spectrometer setting as is customary, we used the method employed in instruments which record the galvanometer deflections automatically. The zero was read before and after each series of measurements, and the results corrected for the sloping base line caused by the zero drift. Some slight discrepancies in the relative intensities of the various bands may be introduced, because of the fact that we must assume that this zero drift was linear with time. Such errors however will be small, for evidence indicates that this drift is linear. One observer changed the spectrometer setting in intervals of 10 \AA , while the other read and recorded the respective galvanometer deflections. By plotting the results thus obtained we got directly a curve showing the energy transmitted (galvanometer deflections) for the various wave-lengths. The minima of these curves gave us the wave-lengths of the absorption bands.

It must be remembered that in using such a method the total energy transmitted at any wave-length is affected by many factors, namely: the emission of the source, the absorption of the atmosphere, the absorption of the empty cell, the absorption of the filter, and finally the absorption of the sample which is being studied. Separate experiments proved that the empty cell and the filter were not selective in their absorptions, but only reduced the values throughout the entire range by a constant factor. By making a series of measurements, with the absorption cell removed entirely, the combined results of the first two effects was obtained. In Fig. 4 (a) and (b) we have drawn two such curves. They are drawn from different base lines so they may be easily compared. Here we see some 65 or more weak bands, which are evidently due chiefly to the water vapor in the air. The trustworthiness and accuracy of the instrument and methods used, are shown by the manner in which the weak minima of these two curves check each other.

RESULTS

Last year⁵ readings were taken at intervals of 0.007μ on an instrument whose calibration was accurate to $\pm 0.0015\mu$ and the wave-lengths then stated were thought to be accurate to $\pm 0.003\mu$. This year readings were taken every 0.001μ , using an instrument calibrated to $\pm 0.0005\mu$, and therefore we believe that we can now state our wave-lengths to $\pm 0.001\mu$.

The absorption of benzene has been measured some 30 odd times this year, under many different conditions. We have used various cells, slit widths and thicknesses of solution. Fig. 4 (c) shows a sample curve for benzene, made with slits 0.1 mm wide (11 \AA 'slit width') and a thickness of 0.05 mm . In comparing this with a curve from last year, we find the same three strong bands located this year at 3.236μ , 3.257μ and 3.296μ . A careful study was made of the weaker indications of absorption lying on each side of the strong

⁵ R. Bowling Barnes, reference 1.

group of bands. It was noticed in the work last year, that while the 3 strong bands always checked in the different curves, these weaker ones rarely ever agreed exactly. By comparing the benzene curve with those for the atmosphere, we can see the reason for this. Since we have the absorption of water vapor superposed upon that of benzene, we must expect the locations of the benzene bands to be somewhat affected by the presence of the water bands. This effect will be rather slight in the case of very strong benzene bands.

Fig. 4. Absorption curves. (a) and (b) atmospheric absorption. (c) benzene, $t=0.05$ mm. (d) benzene, $t=0.1$ mm. (e) benzene, $t=0.5$ mm.

However, in regions where the bands of the two compounds are of approximately the same intensity, a change in the partial pressure of the water vapor present in the room, may produce very noticeable changes in the absorption bands. In the previous work, since readings were taken only every 0.007μ , we always had the combined effect of benzene and water vapor, for neighboring bands could not be separated.

In order to identify further the weak benzene bands, we made measurements on benzene in 5 different thicknesses. Fig. 4 (c), (d) and (e) show a

comparison of 3 such curves, and it is easily seen that on the short wave-length side of the 3 strong bands, benzene has no absorption. However, toward longer wave-lengths several bands show decided changes as the thickness is increased. The bands which show these changes, do not correspond to any of the air bands, and thus we can say definitely just which of the weaker minima indicate benzene bands, and which, water vapor. With this process we finally arrived at the results given for benzene in Table I. Here we have also listed for reference the wave-lengths of the water-vapor bands.

Obviously, if we could eliminate this atmospheric absorption the results could be interpreted more easily and no doubt would be more exact. This could be done by taking one set of values through the compound and then a set through an empty cell, and subtracting the respective ordinates. This, however, would again require zero readings and would thus make the procedure very much longer and harder. The only course which offers a convenient solution to the problem seems to be to enclose the entire spectrometer in a vacuum, or to say the least, in an enclosure which has been carefully freed from water-vapor and CO_2 . The entire instrument from Nernst lamp to thermocouple must be in such an atmosphere. Czerny⁶ enclosed his spectrometer in a tin case, which contained trays of P_2O_5 and KOH . Plans are at hand for putting this instrument into just such an enclosure. Until this is accomplished however, we must continue to use our method of locating the atmospheric bands, and then picking them out of the other absorption curves.

TABLE I. *Wave-lengths of observed bands.*

Air	Air (con)	Air (con)	Air (con)	Air (con)	Benzene	Toluene
3.054 μ	3.193 μ	3.331 μ	3.633 μ	3.748 μ	3.236 μ	3.240 μ
3.073	3.202	3.342	3.642	3.754	3.257	3.263
3.083	3.210	3.348	3.654	3.762	3.296	3.301
3.093	3.217	3.364	3.659	3.768	3.383	3.386
3.098	3.224	3.379	3.664	3.781	3.412	3.426
3.106	3.230	3.397	3.675	3.787	3.440	3.489
3.115	3.241	3.430	3.685	3.801	3.463	
3.127	3.246	3.455	3.697	3.807	3.508	
3.139	3.267	3.485	3.709	3.813		
3.146	3.270	3.498	3.715	3.825		
3.153	3.281	3.512	3.721	3.830		
3.158	3.305	3.603	3.730			
3.178	3.312	3.614	3.736			
3.180	3.321	3.626	3.743			

In this manner, the bands of toluene were also located. Curve (d) of Fig. 5 shows this absorption clearly. The air bands are easily identified. The remaining bands, whose wave-lengths are given in Table I, agree nicely with those stated in the previous paper. Again we note only a slight shift toward longer wave-lengths in the locations of the three strong bands of the benzene C-H's. These shifts are 0.004 μ , 0.006 μ and 0.005 μ respectively. The minimum at 3.307 μ shows up in the other curves for toluene to be due to air. The general intensity distribution throughout this entire region is the same as that shown previously.

⁶ M. Czerny, *Zeits. f. Physik* **34**, 227 (1925).

Curve (b) of Fig. 5 shows an attempt to measure the absorption of cyclohexane at a thickness of 0.05 mm. As is shown in the curve the intensity of the absorption is extremely great. From 3.35μ to 3.46μ this thickness is opaque, the only energy transmitted being the 30 per cent contamination due to 1.75μ . The results were the same, using a film formed by putting one drop of the liquid between two cover glasses, which were then pressed together. Le Compte⁷ gives a curve for it, but does not mention the thickness. He

Fig. 5. Absorption curves. (a) atmospheric absorption. (b) cyclohexane, $t=0.05$ mm. (c) benzene, $t=0.05$ mm. (d) toluene, $t=0.05$ mm.

finds for it bands at 3.16μ , 3.26μ , 3.60μ and 3.90μ . We find the strong band somewhere between 3.35μ and 3.46μ . It is interesting to note that the three benzene bands are entirely absent. In this molecule no C atom has only one H atom attached as in benzene, but each has two. Apparently, the H-C-H vibrations are quite different from the C-H vibrations. Cyclohexene, also shows an extremely strong absorption in this region.

⁷ J. Le Compte, *Le Spectra Infrarouge.*, p. 218.

CONCLUSIONS

Specific heat calculations⁸ and Raman photographs⁹ each show definitely that the C-H linkage must vibrate with a frequency very close to 3.5μ . In most organic liquids then, we must expect to find very complex absorption bands in this region. Remembering that water also has a strong band close to 3.0μ , we see that almost every liquid will have pronounced absorption between 3.0μ and 4.0μ . The resulting fact, that so many liquids have complex bands around 3.5μ , makes this spectral interval a most interesting and fruitful source of information concerning the structure of the molecules. To obtain all of this information we must develop instruments of still higher sensitivity and resolving power. With the present spectrometers however, we can learn quite a bit.

In our first paper we showed several progressive shifts and changes in the bands, which were apparently connected with the symmetry and structure of the molecule. The curve on cyclohexane shows no trace of the three strong benzene bands. This is the first curve in which they have been entirely absent, and this is the first molecule we have examined which had no simple C-H bonds. Toluene and each of the other derivatives had some C-H linkages, in addition to their respective radicals. In these we found separate absorption due to the C-H, CH_3 , C_2H_5 and C_4H_9 groups. Here in cyclohexane the absence of bands for C-H gives us additional evidence, which seems to show a mutual effect between two neighboring C-H bonds. Every shift and intensity change tells something about the molecule, and it is hoped that a theoretical discussion of these will soon appear.

THE EFFECT OF HIGH PRESSURE ON THE NEAR INFRARED ABSORPTION SPECTRUM OF CERTAIN LIQUIDS*

BY J. R. COLLINS

CORNELL UNIVERSITY

(Received June 5, 1930)

ABSTRACT

Certain absorption bands of liquid water, methyl alcohol, amyl alcohol, and toluene were studied when the liquids were subjected to high pressures. In the case of the first three liquids, pressures up to 5000 kg/cm² were used, and pressures up to 8000 kg/cm² were applied to the toluene. No change was found either in the spectral position or in the intensity of the bands studied. The results are of interest since a change in the polymerization of polar liquids is supposed to take place with increase of pressure. The absorption bands are characteristic of the molecules and hence a change in the position and intensity should accompany the change in polymerization. As no such change was observed, it is concluded that there is no change in polymerization in the pressure range studied. The pressure necessary to solidify toluene at 20°C. was found to lie between 8100 kg/cm² and 8300 kg/cm².

INTRODUCTION

THE anomalous properties of liquid water have been explained by the hypothesis that it is composed of two or more kinds of molecules. The simplest assumption is that water consists of the molecules (H₂O)₂ and (H₂O)₃ whose relative proportions depend on the physical conditions such as temperature, pressure, etc. Sutherland¹ has made calculations as to the relative amounts of the two constituents under various conditions of temperature. The author² has studied the near infrared absorption spectrum of liquid water from its freezing point to its boiling point and found changes which seem readily explained on Sutherland's assumptions. Redlich³ has used the author's results to calculate the relative amounts of the two kinds of molecules at various temperatures and finds fair agreement with similar calculations based on the change of magnetic susceptibility of liquid water as the temperature changes.

Sutherland explains the change in the viscosity of water with pressure by assuming that the degree of polymerization changes as the pressure changes. He estimates that a pressure of a few thousand atmospheres should convert all of the triple molecule into the simpler one. Hence, if one may interpret the change in the absorption spectrum as due to a change in the degree of polymerization, the absorption spectrum should show decided

changes as the pressure on the liquid is increased to several thousand atmospheres. Accordingly, the present experiments were undertaken to find if such changes do occur. Although the principal interest is in the case of water, the experiments were planned to include the study of toluene as a typical nonpolymerizing liquid and as many other liquids that do show polymerization as time would permit. The experiments were performed in the Jefferson Physical Laboratory at Harvard University, and the author is under deep obligation to Professor P. W. Bridgman who kindly designed the pressure chamber which provided plane parallel glass windows through which the radiation could be passed through the specimen.

APPARATUS AND EXPERIMENTAL PROCEDURE

The method of measurement was to pass a beam of radiation from an incandescent source through the chamber containing the liquid, to disperse the radiation by means of a spectrometer system and then to measure the intensity of the radiation at the exit slit of the spectrometer by means of a thermopile and galvanometer. On account of the impossibility of moving the absorption chamber, an indirect method of obtaining the fractional absorption of the liquid at the various pressures was used. Figure 1 illustrates

Fig. 1. Diagrammatic arrangement of apparatus.

diagrammatically the arrangement of apparatus. *L* is the filament of a street series incandescent lamp, from which two beams of parallel radiation are obtained. One of these beams passes through the absorption chamber *C* and is then focussed on the entrance slit of the spectrometer system. The other beam, after reflection from suitably placed mirrors, is also focussed on the slit of the spectrometer. By means of the shutter *G*₁ either of these beams may be blocked off and the intensity of the other measured by the thermopile. The beam which does not pass through the specimen serves as a standard of comparison, so that the absorption at any one pressure can be calculated if that at any other pressure is known. The absorption at atmospheric pressure was determined by a separate experiment.

The spectrometer used was a double Van Cittert spectrometer in which the slit S_2 is moved across the spectrum focussed in its plane. This movement allows any desired spectral position to be transmitted through the system. The double spectrometer is necessary to obtain the necessary purity of spectrum. The spectrometer was calibrated by means of emission lines from a mercury arc, and by means of the known positions of absorption bands of several liquids. Since the openings at the ends of the absorption chamber were only one quarter of an inch in diameter, the amount of radiation transmitted was very small. It was accordingly necessary to use a thermo-relay to magnify the galvanometer deflections. It was found that a magnification of fifty times was sufficient, and the Moll thermo-relay used was very steady at this magnification. On account of mechanical and electrical disturbances which were present in the daytime, all measurements were made at night.

Figure 2 shows the details of the mounting of the glass windows in the ends of the absorption cell. *A* is the window and was a cylinder of glass seven eighths of an inch in diameter and one and a quarter inches thick. A doubled piece of rubber tubing, *E*, was tightened around this window by

Fig. 2. Detail of mounting the windows in the pressure chamber.

means of the tube, *D*, and made a liquid tight seal between the window and holder *C*. This holder was forced in against the shoulder of the cell by means of the screw plug *B*. Packing at *F* was used to make the outside edge of the holder tight. When pressure was applied to the inside of the chamber, the window *A* was forced to a seat against the bottom of the holder. A thin washer of tin was placed between the window and bottom of the holder.

With plate glass as the material of the windows, pressures up to 10000 kg/cm² could be maintained for long periods of time. Unfortunately, however, plate glass has a strong absorption band in the spectral region being studied, and with the two windows only about one percent of the incident radiation was transmitted. Although several kinds of transparent glasses were tried, none were found which would allow pressures greater than about 5000 kg/cm² to be maintained for any length of time. Another arrangement which was used in the last part of the experiments was that described by Poulter,⁴ which allowed thin windows of plate glass to be used. These windows transmitted sufficient radiation to be measured. The holder, *C*, was

⁴ Poulter, Phys. Rev. 35, 297 (1930).

made solid and the inner end ground and polished to a plane surface. Then windows five sixteenths of an inch were cemented on to the end of the holder by a very thin layer of Canada balsam.

The original plan was to have the specimen placed in an absorption cell inside the pressure chamber so that the liquid transmitting the pressure would not contaminate the specimen. However, every liquid suitable for the transmission of pressure has strong absorption bands in the spectral region being studied, and so in the final arrangement the specimen filled the whole pressure chamber and as much of the pressure chamber above the absorption chamber as was possible without affecting the manganin coil whose resistance was measured as an indication of the pressure. Kerosene was used to transmit the pressure to the specimen liquid. A capillary tube connected the absorption chamber with the pressure producing apparatus and diffusion of the kerosene through this tube was apparently slow enough to prevent harmful contamination of the specimen. The test of this was to measure the absorption of the specimen after the pressure had been on for some time and then reduced to atmospheric pressure again. No change was noticed which could be ascribed to contamination of the specimen.

The procedure was as follows. The apparatus was assembled and a small pressure applied to find if the packing was liquid tight. Then by means of the shutters G_1 and G_2 the intensity of the two beams of radiation were obtained for various settings of the spectrometer system through the spectral region desired. Then the pressure was raised to about 1000 kg/cm² and the process repeated. Pressures higher than 5000 kg/cm² were not obtained under circumstances which permitted measurements of the absorption except in the case of toluene. This was possibly due to faulty assembly, although the same care was taken in all cases. This pressure is well in excess of that estimated by Sutherland for the complete conversion of the triple molecule of water into the simpler form.

A very interesting method of obtaining the pressure necessary for the solidification of toluene at 20° C. was to observe the interior of the pressure chamber by means of a reading telescope. When the pressure was slowly increased, fine needle like crystals would begin to form, and if the pressure was maintained, the whole of the liquid would become solid. On slowly reducing the pressure, the crystals would begin to melt. As the pressure was successively raised and lowered above and below the solidification point, the pressures at which the solidification and the melting took place came nearer to each other and after a great many trials, the final values obtained were: Freezing pressure 8300 kg/cm², melting pressure 8100 kg/cm².

RESULTS AND CONCLUSIONS

The results obtained for five absorption bands of water indicate that there is no change in the spectral position or intensity of the bands. The absorption bands of water which are studied are supposed to be the overtone bands of fundamental bands farther in the infrared. It was expected that these might show even greater changes than the fundamental bands would

show. Also they are not so intense as the fundamental bands so that reasonable thicknesses of the liquid could be used. When too thin layers are used, the thickness is increased at the higher pressures on account of the packing becoming compressed and thus allowing the windows to move outward. Only a few of the curves which were obtained are shown as they are all similar in that no change in spectral position is shown and only slight changes in intensity. These changes in intensity are ascribed to the increase in length mentioned above. Account was taken of the increase in density of the liquid as the pressure was increased.

A study of the absorption of toluene was made as an example of a non-polarizing liquid and thus, presumably, of a liquid whose molecules do not

Fig. 3.

Fig. 4.

associate to produce complicated molecules. The two alcohols were studied as other examples of polymerized molecules.

Results are plotted for the lowest and highest pressures used as the results for the intermediate pressures lie intermediate between them. In the case of water several runs were taken at each absorption band and the results plotted are from one of the individual runs.

If we are to assume that changes in the absorption bands of a liquid should occur when the degree of polymerization changes, the results of these experiments indicate that no such change in polymerization occur in the pressure range used. It is difficult to imagine a process whereby an increase in pressure would cause a breaking up of the complicated molecules. Bridgman,⁵ in discussing the effect of pressure on the thermal expansion of water, concluded that his results do not indicate any breaking up of the complicated

Bridgman, Proc. Am. Acad. Arts, and Sci. 47, 544 (1912).

molecules. From other considerations, he concludes that the effect of pressure should be one of increasing the complexity of the molecules.

It is interesting in this connection to note that Stewart⁶ denies the existence of small molecular groups such as are postulated by Sutherland and others. His results on the x-ray diffraction halos produced by liquid water lead him to postulate the presence of very large groups of molecules with a regular arrangement, these groups having only a temporary existence to be succeeded by other similar groups. The results of the present experiments

Fig. 5.

Fig. 6.

do not seem incompatible with this view of Stewart, as it seems likely that the absorption of the molecules within these groups would be different than that of the molecules not in the groups, and that there may be some effect of temperature on the number of molecules in the groups or on the time of existence of a given group.

The author wishes to make grateful acknowledgment of his indebtedness to Professor Bridgman for placing the pressure apparatus at his disposal. The author also feels under obligation to Mr. Mann, chief mechanic at Jefferson Laboratory, who helped by his skill and advice.

ADSORPTION OF METHYL ALCOHOL FILMS ON ROCK-SALT

BY SHIRLEIGH SILVERMAN
JOHNS HOPKINS UNIVERSITY

(Received June 9, 1930)

ABSTRACT

The optical method of Rayleigh and Drude as recently modified by Frazer and Herzfeld has been applied to the study of methyl alcohol films on rock-salt. The isothermal adsorption has been studied at pressures ranging from 10^{-5} mm to 11 cm mercury. The results indicate that a unimolecular layer is formed at a pressure between 10^{-5} and 10^{-4} mm of mercury, with no further adsorption until the region of 2-3 cm, when a second layer begins to form, with completion at 9-10 cm. The thickness of these layers is calculated to be in the neighborhood of 4.5-5.0Å. The effect of thorough outgassing has been observed and the results have been interpreted to indicate that with decrease in temperature either an underlying unimolecular layer of water vapor is formed, or that there is a true increase in the natural ellipticity of the surface. In addition, it is possible to calculate the isothermal heat of adsorption from the experimental data.

INTRODUCTION

IF A beam of light be allowed to fall upon a plane surface of a transparent medium at the polarizing angle, the reflected beam is not found to be completely plane polarized, but is always elliptically polarized. Drude¹ has shown that the ellipticity of the reflected beam may be explained by assuming that there is not a perfectly sharp boundary between the two media, but that there is present a transition layer whose properties vary from the rare to the dense medium. This sheet whose index of refraction gradually changes from the value of 1 (assuming the 1st medium to be air or vacuum) to n , the refractive index of the 2nd substance, is known as the transition layer. Drude has worked out the equation which yields the relation between the observed ellipticity and the thickness of the transition layer; where we define as the ellipticity the ratio of the amplitudes of the minor and major axes of the ellipse of polarization.

The result is as follows:

$$\rho = \frac{\pi}{\lambda} \frac{(\epsilon_1 + \epsilon_2)^{1/2}}{\epsilon_1 - \epsilon_2} \int \frac{(\epsilon - \epsilon_1)(\epsilon - \epsilon_2)}{\epsilon} dz \quad (1)$$

where ρ is the ellipticity, ϵ_1 , ϵ and ϵ_2 are the dielectric constants of the first, the transition, and the second media respectively, λ the wave-length of the incident light, and z the position in the transition layer.

It is possible to determine a lower limit for the value of the thickness of the layer, L , which will not deviate very greatly from its true value. For a

¹ Drude, Theory of Optics, p. 287, Longmans (1901).

given value of ρ it is evident that L will attain its smallest value when ϵ is assumed to be a constant whose value is determined by making the factor $(\epsilon - \epsilon_1)(\epsilon - \epsilon_2)/\epsilon$ a maximum. This condition will be fulfilled when $\epsilon = (\epsilon_1 \epsilon_2)^{1/2}$. Setting the refractive index equal to the square root of the dielectric constant, the expression for the lower limit of L becomes:

$$\frac{L_{min}}{\lambda} = \frac{\rho}{\pi(1 + n^2)^{1/2}} \frac{n + 1}{n - 1} \quad (2)$$

where n is the refractive index of medium 2 with respect to medium 1.

Work by Langmuir, and later by Eucken, has formed the background for the theory that adsorption takes place in uniform monomolecular layers, and that each layer is completed before the formation of a subsequent one. Many other workers have substantiated this theory. However, many experimenters have worked with glass surfaces, with the resultant difficulty that it is very hard to describe the exact condition of the surface; to say nothing of the elaborate set-up required for the volumetric measurements on such large surfaces. Now, an adsorbed film fulfills the condition of Drude's transition layer. So, by taking a small cleavage surface of a crystal (two or three millimeters square was found to be quite large enough) which reflects nearly as well as plate glass, it is possible to calculate directly the thickness of the adsorbed layer by observing the changes in the ellipticity of the reflected light. The materials selected for this experiment were rock-salt for the transparent medium, because of the relative ease with which a perfectly clean surface may be prepared; and methyl alcohol for the vapor, because of the insolubility of rock-salt.

The equations of Drude require that the amplitude of the incident light in the plane of incidence be equal to the amplitude in the direction perpendicular to the plane of incidence. In early work on the measurement of thin films by Drude¹ and Rayleigh² the incident light is polarized at an angle of 45° at the plane of incidence. The ellipticity was measured by means of a Babinet compensator. Other investigators; Ives and Johnsrud³ and Ellerbroeck,⁴ have measured films; but in no case with an accuracy greater than several Angstrom units. The method has been considerably improved in this laboratory by Herzfeld and Frazer,⁵ and an accuracy of 3/10 to 4/10 Å has been attained. The essential improvements are: (1) the incident light is unpolarized, giving greater intensity while fulfilling the conditions set by the theory. (2) the ellipticity is measured photometrically with an accuracy unobtainable with a compensator. The present apparatus is very similar to that used by the above mentioned authors, with a few added refinements, particularly in the photometric arrangement.

The apparatus is shown diagrammatically in Fig. 1. The source of light was an Edison 500 C. P. Pointolite which gives a very intense beam that is

quite uniform. After passing through a pin hole S_1 , the image of the hot tungsten plate was brought to a focus on a second pin hole S_2 and the beam made parallel by lens L_3 . A piece of clean plate glass M_1 was placed at a very slight angle to the beam, the transmitted light being allowed to fall upon the crystal and the reflected beam being used as the comparison beam in the photometer. The transmitted beam was reflected from the crystal R at the polarizing angle, passed through the analyzing nickel and brought to focus upon a piece of lightly ground glass G_1 . This serves to produce a very uniform field in the photometer. The beam is then made parallel by a lens L_5 , is passed by the edge of the mirror M_3 through the photometer P and the filter A , to the eye. The comparison beam was reflected successively from the mirrors M_1 and M_2 , brought to focus upon a bit of ground glass G_2 which formed a pin hole S_3 ; behind this was placed the photometric wedge W . The beam is again made parallel, and is reflected from the photometer mirror M_3 through the filter A to the eye.

Fig. 1. Diagram of apparatus.

The photometer was of the Pfund split-field type, which consists of a mirror of a very sharp edge, set at an angle of 45° to the incident beams. One ray passes by the edge of the mirror and the other is reflected by it. The wedge was selected to give a linear transmission curve between ten percent and sixty percent; and was neutral as far as could be determined spectrophotometrically. In addition, screens were used which were calibrated against the wedge, and checked upon the same spectrophotometer. Inasmuch as the wave-length enters Drude's formula it is necessary to use a color filter. For this purpose, an aniline solution was found to be preferable to a monochromator since the intensity of the transmitted light is much greater. Such a solution was prepared by Professor Pfund, and the spectral centroid (5550A) calculated to an accuracy of about one percent.

The vacuum system itself merits a brief description. To prevent, as far as possible, contamination by stop-cock grease and occluded water vapor, a tube of activated coconut charcoal was placed between the crystal container and the rest of the system. The charcoal was previously outgassed by repeated heating to a dull red heat until no further gas was driven off. To make

certain that there was no backing-up on the far side of the charcoal plug, and auxiliary tube was connected to the container after the end of the main experiment. Pressure readings were found to be the same on both sides of the charcoal. The alcohol is kept in a trap and the vapor admitted as desired through a small stop-cock which was kept on the far side of the charcoal. The low pressures were read on a McLeod gauge. This was believed to be reliable as the pressure difference in the gauge at the highest pressures read was only 1.5 centimeters of mercury which is considerably below condensation pressure. As for occlusion of gases in the capillaries of the gauge, it was found that repeated pressure readings were quite consistent, so that it was not likely that our readings were affected. Higher pressures were read on the manometer.

EXPERIMENTAL PROCEDURE

The experimental procedure was as follows: a piece of rock-salt which was free of cloudiness was ground and polished along one edge at an angle of about 20° to the nearest cleavage plane. It was then cracked along the nearest cleavage direction and placed immediately in the container at the polarizing angle; and the apparatus was evacuated immediately. The polishing of the back plane at this angle of 20° removed entirely any reflection from the rear surface which would have vitiated our readings. The bottle containing the crystal was then heated and pumped out at a fairly good vacuum, 10^{-5} millimeters of mercury, for some hours. Methyl alcohol was admitted and the pressure noted; the nicol prism was set for minimum and maximum transmission, and the square root of the ratio of the readings gave the value of ρ . The temperature was measured and kept constant to within 5°C . The pressure was varied, and the readings taken again. This was repeated until the whole range between 10^{-5} mm and 11 cm had been covered. The temperature was then raised to the desired value, and the set of readings repeated. The alcohol was supplied by the Chemistry Department; no traces of water vapor or of any volatile organic substances were listed among the impurities.

Certain precautions were found to be quite necessary; (1) It is exceedingly important that no water vapor be present to be adsorbed on the surface; (2) No stop-cock grease or metal should be used in the set up as they might contaminate the surface; (3) The windows of the outfit must be free of double refraction; (4) The pressure in the gauge has to be corrected to give the pressure in the container as there is a temperature difference. As for the first precaution, it is impossible to state at present whether or not all traces of water vapor can be removed, even by continued heating at temperatures around 325°C . This will be discussed more fully at the end of the article. The second contamination was avoided more readily. The crystal was imbedded in a bead of molten silver chloride at the end of a glass rod, and the upper end of the rod was ground nicely to fit into a tube; no lubricant was used. This arrangement permitted very easy adjustment of the angle of reflection, and after the crystal was set at the polarizing angle, the tube was

sealed off. The windows were of Pyrex plate glass, which were very carefully annealed and tested between crossed nicols after being sealed to the container. To further test for double refraction a specimen was taken and its ellipticity determined in air and in the apparatus. The two values were identical. Knudsen's equation for the relative pressures on the two sides of a porous plug at absolute temperatures T_1 and T_2 respectively, is:

$$\frac{p_1}{p_2} = \frac{T_1^{1/2}}{T_2^{1/2}} \quad (3)$$

This equation fits our condition fairly closely for low pressures, and the correction was applied to all our low pressure readings; at high pressures the temperature correction is small enough to be neglected.

It was found possible to read the photometer to an accuracy of two percent. Accordingly, a group of eight or nine settings was taken for each reading, so that the probable error was quite close to one percent. Now,

Fig. 2. Adsorption isotherms.

Fig. 3. Adsorption isotherms.

for $\lambda = 5550\text{\AA}$, a value of $p = 0.01$ means a layer about 45\AA thick. The values of p range from 0.0125 to 0.0170, so that the absolute error was about 0.5\AA . This is the same percentage error, but a slightly larger absolute error than is claimed by Frazer.⁵ In all cases the adsorption is found to be completely reversible, and an adsorbed layer can be removed at will, returning the surface to its original condition.

EXPERIMENTAL RESULTS

At 325°C and 10^{-5} mm pressure the ellipticity had a value of 0.01265. The value remained unchanged at twice this pressure and then increased to a value of 0.01365 at 2×10^{-4} mm from this pressure up to the neighborhood of 2 cm there was no further change in the ellipticity. From this point, the value increased linearly until 9.5–10 centimeters was reached, after which there was an abrupt increase in the ellipticity. The isothermal corresponding to 300°C showed a very similar curve, parallel and higher than the one at 325°C . At 10^{-5} mm the value was 0.0127, and above 10^{-4} mm the value was

0.0137. The same flat region extending to two or three centimeters was noticed, and the following portion proceeded as in the first case. The curves were repeated for intervals down to 75°C. In all cases the adsorption at lower pressures occurred roughly between 10^{-5} mm and 10^{-4} mm, and in all cases there was no further change until the neighborhood of two to three centimeters had been reached. Further, the ellipticity following two centimeters proceeded regularly until ten centimeters was reached. These curves are shown in Figs. 2 and 3.

Fig. 4. Ellipticity as function of temperature. ($p=10^{-5}$ mm)

Lastly, the outfit was outgassed and the pressure was lowered to 10^{-5} mm, the temperature being 325°C. The pressure was kept constant and the temperature lowered progressively to 70°C, with readings being observed at intervals of about 50°C. The apparatus was then heated for three days at 325°C and 10^{-5} mm; it was then cooled over-night. Following, it was heated under the same conditions continuously throughout a period of four days. Readings were again taken at various temperatures as the cooling progressed. As will be seen from Fig. 4 at 325 degrees, the two curves coincide; their divergence is noticeable at 250°C, while at 100°C the increase in ellipticity for the clean surface in air is about 0.0008, and the corresponding increase for the surface in the presence of methyl alcohol is 0.00205.

INTERPRETATION AND DISCUSSION

The results of the preceeding section are summarized in the following table:

Temp.	$\Delta\rho_1$	$\Delta\rho_2$	L_1	L_2
325	0.0009		4.1A	
300	.00095		4.3	
275	.0011	.0011	4.9	4.9A
225		.0012		5.4
200	.0014		6.3	
175		.0009		4.1
100		.0008		3.6
75		.0008		3.6

Where $\Delta\rho_1$ is the change in ellipticity in the approximate interval of 10^{-5} to 10^{-4} mm and $\Delta\rho_2$ the change in ellipticity in the approximate interval of

2–10 cm; L_1 and L_2 are the respective thicknesses in Angstroms corresponding to $\Delta\rho_1$ and $\Delta\rho_2$. The average value of L_1 is 4.9A, and the average value of L_2 is 4.3A. These values agree fairly well with values calculated by means of the kinetic theory. Pictorially, this means that the first layer of methyl alcohol molecules first begins to be adsorbed on the surface at pressures slightly above 10^{-5} mm, and that the layer is complete at pressures slightly above 10^{-4} mm. The alcohol molecule is probably oriented with its long axis perpendicular to the surface, with the OH radical adjacent to the Na ions of the lattice. From the pressure of about 10^{-4} mm until the region of 2–3 centimeters there is no further adsorption. At this point the formation of a second layer commences, and becomes complete at around 9.5–10 cm. Whether or not the second layer is oriented cannot be said definitely, as the binding forces must be considerably weaker than in the case of the first layer.

While the interpretations of the isotherms are apparently clear, it is much more difficult to explain the changes with temperature. The curves of

Fig. 5. Adsorption isotherms referred to a common origin.

Fig. 4 seem to show that the surface is clean at 325°C, so that the measured ellipticity must be natural to the clean surface. The increase in ρ with decrease in temperature may be explained in one of two ways. First, as the temperature is lowered, a single layer of water vapor might begin to form which is complete at temperatures around 100°C. This would mean, then, that at high temperatures there is adsorption only of methyl alcohol, but that at lower temperatures adsorption of both methyl alcohol and a layer of water vapor is observed. The second possibility is that there is no water vapor present and that the increase in ellipticity is indicative of an actual surface roughening with lowering of temperature. Very recently, Frazer⁶ has observed the same type of curve with an agreement which is very encouraging. He attributes the increase in ellipticity to an adsorption of air; however, this is rather unlikely. The only possible constituent of air that would be likely to adsorb so strongly would be water vapor. However, there is nothing conclusive to be drawn from the data thus far. Certain modifications in the crystal container will have to be introduced, as it does not now appear that outgassing by heat alone is sufficient to determine whether all traces of water vapor have been removed.

If the effect is actually due to temperature directly, then we can move the curves of Fig. 2 to a common origin at their lowest points as in Fig. 5. This will then give us a family of curves of true adsorption. Then it is possible to calculate the isothermal heat of adsorption by means of the Clausius-Clapeyron equation:

$$\frac{d(\log p)}{dT} = \frac{Q}{RT^2} \quad (4)$$

The approximate values obtained are: 7000 calories for the first layer and 2000 calories for the second layer, in the region of 250°C. However, theoretical considerations seem to be in favor of the first view as the theoretical value of Q is several times larger. If at 325°C the alcohol is adsorbed directly on the salt we could use as a rough approximation the following formula which is due to Nernst:

$$\log p = -\frac{Q}{4.51T} + 3 + 1.75 \log T \quad (5)$$

which, with a value of $p = 10^{-4}$ mm and $T = 600^\circ\text{K}$, yields a value of 40,000 calories per mol. On the other hand one can calculate the energy between an ion and a dipole of moment⁶ P , which is (PeN/r^2) ergs per mol. If we accept for r the value calculated from the hydration of the sodium ion, $r = 1.74\text{\AA}$, for P the value 1.7×10^{-18} ; one again finds for the value of Q about 40,000 calories per mol. On the other hand, we find for 200°C almost the same pressure, which would make Q about 21,000 calories; this decrease can best be accounted for as being due to an adsorption on a partly water covered surface. But the value of 7,000 calories as found experimentally is far too small to account for the vapor pressure as small as 10^{-4} mm at 300°C. One might state the argument in another form. One can expect that the equilibrium pressure of an adsorbed monomolecular layer and the vapor pressure of the substance in bulk to be similar, if the heat of adsorption and the heat of evaporation are similar. Water, with a heat of evaporation of about 9500 calories boils at 100°C; mercury with 13000 calories boils at 338°C. As the equilibrium pressure in the present case is 10^{-4} mm at 325°C, the heat of adsorption must be considerably higher than 13000 calories.⁸

The author wishes to take this opportunity to acknowledge many useful suggestions of Professor A. H. Pfund, concerning the optical set-up; and to express his sincere thanks to Professor Karl F. Herzfeld who has suggested this problem and whose assistance and supervision during its growth have been most helpful.

THE PRINCIPAL MAGNETIC SUSCEPTIBILITIES
OF BISMUTH SINGLE CRYSTALS

BY ALFRED B. FOCKE

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA, CALIFORNIA

(Received June 9, 1930)

ABSTRACT

The Gouy method is used to determine the principal magnetic susceptibilities of bismuth single crystals grown by the method developed by Goetz. The specific susceptibility is shown to be a constant in all directions perpendicular to the principal crystallographic axis with a value of -1.487×10^{-6} . Parallel to the main axis the specific susceptibility is a minimum and has the value -1.046×10^{-6} . The mean is given then as -1.340×10^{-6} .

I. HISTORICAL

RECENT investigations by Goetz,¹ Goetz and Hasler,² and Goetz and Focke,³ concerning the effects of allowing one half of a single crystal of bismuth to crystallize in a strong magnetic field, have shown that different orientations are affected in different ways. The effects are a maximum if the principal axis is perpendicular to the field and a minimum if the axis is parallel to the field. This at once leads to the conclusion that if the susceptibility is a contributing factor in the effect, it must also have a maximum perpendicular to the main axis and minimum parallel to it. This supposition is sustained by the results obtained by Nusbaum.⁴ There is however an objection to accepting the absolute values of the results which he has reported since the value given by him as the maximum is still below that given in tables for the susceptibility of the heterogeneous crystal aggregate. Because of this, it was felt that a new determination of the principal susceptibilities of bismuth should be made.

II. PREPARATION OF CRYSTALS

The bismuth used in the crystals described in this paper was obtained from the Braun Corporation and subsequently vacuum distilled in an effort to purify it.

The single crystals were made by the method developed by Goetz.¹ Crystals are grown in this method, by moving a rod of the metal which is lying in a graphite trough through a furnace at such a speed that once a crystal begins to form, it can continue its growth throughout the entire rod, the orientation of the crystal being determined by inoculation. The orientations used were P_1 (principal axis perpendicular to the length of the rod) and P_3 (principal axis parallel to the length of the rod). The

⁴ C. Nusbaum, Phys. Rev. 29, 905 (1927).

accuracy of the orientations could be checked after magnetic observations were taken by cleaving the crystal along the basal cleavage plane. In the case of the P_1 crystals, this plane was parallel to the rod making it possible to obtain a very accurate determination of the orientation. The crystals used were all correct to less than ten minutes of arc. The P_3 orientation could not be checked so accurately in this way since the cleavage plane is perpendicular to the rod but as no error could be noticed it was probably accurate to within two degrees.

The crystals were searched for strangers and twinning lamellae before and after the observations, by etching them in nitric acid. Only those crystals which were free from these imperfections were used as any such irregularities would have destroyed the accuracy of the results.

3. METHOD OF MEASUREMENTS

The Guoy method⁵ was chosen for making these measurements. The principal requirement of this method is that the sample must have a uniform cross section over the entire section in which the field gradient is appreciable. The condition of the extreme ends is not important as they are both located in uniform fields. Both of these facts were advantageous because long uniform single crystals were available and also the twinning lamellae at the ends of the crystals, which invariably are formed when bismuth is cleaved, would be in such a position as to have no effect upon the results.

The arrangement is shown in Fig. 1.

Fig. 1. Arrangement of apparatus.

An aluminum suspension S was designed to take the place of one of the regular pans of a sensitive analytical balance B . It was fitted with a divided

⁵ E. C. Stoner, *Magnetism and Atomic Structure*, p. 40, (1926).

torsion head T so that the sample could be rotated about the vertical axis. The lower end of the suspension was about eight centimeters above the pole pieces P of the magnet. This distance was great enough so that the suspension was totally unaffected by the magnetic field. The pole pieces were flat faced and ten centimeters in diameter, giving a very uniform field between them with comparatively little stray field. The crystals C were thirteen centimeters in length, thus placing the lower end on the axis of the pole pieces while the other end was in a field of negligible intensity.

The balance, suspension, crystal and the ends of the pole pieces were enclosed in a cabinet to prevent air currents from disturbing the apparatus.

The greatest error to be expected between any two determinations of the susceptibilities was about 2 percent. The greatest single source of error was in the determination of the area of the cross section of the crystals. Due to the peculiar shape caused by the method of growth, the only practicable way of measuring the cross sectional area was by computing it from the weight, length and density of the sample under consideration. The error thus introduced was about 1 percent. The field strength was measured with a Grassot fluxmeter introducing a possible error of 0.5 percent, and the force exerted upon the crystal by the field was accurate to within 0.3 percent. The greatest deviation actually observed was less than 1.5 percent.

4. THEORY OF THE METHOD

Let a crystal with principle susceptibilities k_1, k_2, k_3 be placed in a magnetic field as in Fig. 2.

Fig. 2. Arrangement of crystal in magnetic field.

Take a set of axes parallel to the principal magnetic axes of the crystal with origin at its lower end.

Let z be parallel to the length of the crystal and let x make an angle θ with the magnetic lines of force. The boundary conditions will then be

$$H_x = H \cos \theta \quad H_y = H \sin \theta \quad H_z = 0$$

$$\frac{\partial H_x}{\partial x} = \frac{\partial H_x}{\partial y} = \frac{\partial H_y}{\partial x} = \frac{\partial H_y}{\partial y} = \frac{\partial H_z}{\partial x} = \frac{\partial H_z}{\partial y} = \frac{\partial H_z}{\partial z} = 0$$

if the diameter of the crystal is small in comparison to that of the pole-pieces.

The equation for the energy of a magnetic field in an anisotropic medium is given as

$$E = \frac{1}{8\pi}(\mu_x H_x^2 + \mu_y H_y^2 + \mu_z H_z^2)$$

where

$$\mu_x = 4\pi k_x, \mu_y = 4\pi k_y, \mu_z = 4\pi k_z$$

thus

$$E = \frac{1}{2}(k_x H_x^2 + k_y H_y^2 + k_z H_z^2).$$

The force in directions parallel to the axes is

$$F_x = \frac{\partial E}{\partial x} = \frac{k_x}{2} \frac{\partial H_x^2}{\partial x} + \frac{k_y}{2} \frac{\partial H_y^2}{\partial x} + \frac{k_z}{2} \frac{\partial H_z^2}{\partial x}$$

$$F_y = \frac{\partial E}{\partial y} = \frac{k_x}{2} \frac{\partial H_x^2}{\partial y} + \frac{k_y}{2} \frac{\partial H_y^2}{\partial y} + \frac{k_z}{2} \frac{\partial H_z^2}{\partial y}$$

$$F_z = \frac{\partial E}{\partial z} = \frac{k_x}{2} \frac{\partial H_x^2}{\partial z} + \frac{k_y}{2} \frac{\partial H_y^2}{\partial z} + \frac{k_z}{2} \frac{\partial H_z^2}{\partial z}$$

or

$$F_x = k_x H_x \frac{\partial H_x}{\partial x} + k_y H_y \frac{\partial H_y}{\partial x} + k_z H_z \frac{\partial H_z}{\partial x}$$

$$F_y = k_x H_x \frac{\partial H_x}{\partial y} + k_y H_y \frac{\partial H_y}{\partial y} + k_z H_z \frac{\partial H_z}{\partial y}$$

$$F_z = k_x H_x \frac{\partial H_x}{\partial z} + k_y H_y \frac{\partial H_y}{\partial z} + k_z H_z \frac{\partial H_z}{\partial z}$$

Substituting the boundary condition these equations reduce to:

$$F_x = 0$$

$$F_y = 0$$

$$F_z = k_x H_x \frac{\partial H_x}{\partial z} + k_y H_y \frac{\partial H_y}{\partial z}$$

$$F_z = k_x \cos^2 \theta H \frac{\partial H}{\partial z} + k_y \sin^2 \theta H \frac{\partial H}{\partial z}$$

$$F_z = [k_y + (k_x - k_y) \cos^2 \theta] H \frac{\partial H}{\partial z}$$

if $H=H$ when $z=0$ and $H=H_0$ when $z=z$ integrating over the volume we get

$$F = \int F_z dv = \int [k_y + (k_x - k_y) \cos^2 \theta] dx dy dz H \frac{dH}{dz}$$

or

$$k_y + (k_x - k_y) \cos^2 \theta = \frac{2}{(H^2 - H_0^2)} \frac{F}{A}.$$

If F is given in grams we have

$$k_y + (k_x - k_y) \cos^2 \theta = \frac{2gF}{A(H^2 - H_0^2)}.$$

In terms of the specific susceptibility x and if $H_0 \ll H$, we have

$$x_y + (x_x - x_y) \cos^2 \theta = \frac{2gF}{dAH^2}.$$

The similarity between this equation and that usually given for the Gouy method is seen at once by setting $x_x = x_y$ giving

$$x = \frac{2gF}{dAH^2}.$$

5. DISCUSSION OF RESULTS

Fig. 3 shows the result obtained when the principal axis of the crystal is parallel to the rod (P_3). In this case the axis is always perpendicular to the

Fig. 3. Variation of specific susceptibility when major axis is parallel to length of the rod.

field and the distribution of the susceptibility in a plane perpendicular to the main axis is measured. It is seen at once that there is perfect circular symmetry about this axis.

Fig. 4 shows a compilation of five separate determinations of the variation of the susceptibility when the main axis is perpendicular to the rod, and a cosine square curve calculated from the average maximum and average minimum values of the susceptibility obtained in the cases of the five individual determinations. In the case of the maximum value the P_3 case is included. The agreement is evident showing that the variation definitely follows a cosine square law.

The principal susceptibilities of this bismuth may be given as $x_{min} = 1.046$ parallel to the main axis and $x_{max} = 1.487$ perpendicular to the main axis. The ratio of x_{max}/x_{min} is 1.425. This last point is particularly mentioned as it has been found that this ratio varies with varying amounts of impurities and an investigation of this effect is now in progress.

The susceptibility, calculated from these values, for a heterogeneous crystal aggregate is $-1.340, (2x_{max} + x_{min})/3$ agreeing very well with the values given in various tables.

Fig. 4. Variation of specific susceptibility when major axis is perpendicular to length of the rod.

DISCONTINUOUS CHANGES IN LENGTH ACCOMPANYING THE
BARKHAUSEN EFFECT IN NICKELBY C. W. HEAPS AND A. B. BRYAN
RICE INSTITUTE, HOUSTON, TEXAS

(Received May 15, 1930)

ABSTRACT

A heterodyne beat method is described by means of which displacements as small as 9×10^{-9} cm may be measured. When a nickel wire, 1.96 cm long and 0.01 cm in diameter, is subjected to a steadily changing magnetic field there is evidence of a sudden length change at the instant of a Barkhausen discontinuity of magnetization. For a nickel wire 2 cm long and 0.002 cm in diameter these sudden length changes were larger and could easily be measured. They were associated with every Barkhausen jump observed in the specimen. The largest one measured was 4.7×10^{-7} cm. Calculations based on the measurements of these magnetostrictive jumps give 3.7×10^{-7} cc. for the minimum value of the volume of the element which suffers the jumps. Reasons are advanced for believing that the sudden change in intensity of magnetization of this volume element cannot be less than 40 units nor more than 330. A qualitative theory of the phenomenon is given.

WHEN a ferromagnetic substance is magnetized by a field which changes continuously it is found that a part at least of the resulting change in intensity of magnetization takes place in sudden discontinuous jumps. This Barkhausen effect is usually observed by means of the induced voltages in a coil surrounding the specimen. Ferromagnetic substances also undergo a change of length when magnetized. There appears to be a very close relation between the magnetostrictive effect and the Barkhausen effect. One phenomenon has so far not been observed in a substance without the other, and both are affected by heat treatment and by mechanical strain.

It seemed probable therefore, that the discontinuities of magnetization should be accompanied by discontinuous changes in length of the specimen. This conclusion follows directly from one interpretation of McKeehan's¹ theory of atomic magnetostriction and is also in agreement with a theory of the Barkhausen effect which has been discussed by one of the authors.² In the experiments to be described a very sensitive and quick acting apparatus has been constructed and sudden changes in the length of a nickel wire have been observed to occur simultaneously with the Barkhausen discontinuities.

APPARATUS

The heterodyne beat method of measuring small capacity changes or small displacements is used. The apparatus, shown diagrammatically in Fig. 1, is a modification of that previously used by one of the authors.³ Oscillator A

¹ L. W. McKeehan, Jour. Frank. Inst. 202, 737 (1926).

² C. W. Heaps and J. Taylor, Phys. Rev. 34, 937 (1929).

³ A. B. Bryan, Phys. Rev. 34, 615 (1929).

is maintained at 1819 k.c. by a quartz crystal. Oscillator B , employing a shield grid tube, is the same as in the previous work except that different condensers are used. C_1 is a calibrated General Radio precision air condenser and is used for purposes of adjustment and calibration. C is a small condenser with two circular horizontal plates 2 cm in diameter. The top plate is supported by a 2 cm length of the nickel wire to be examined. It is steadied and vibrations are damped out by three short sections of rubber cut from ordinary rubber bands, arranged to press downward at three points on its upper surface. The lower plate is provided with a screw adjustment so that the spacing between the plates can be made very small. C is mounted near the center of the large solenoid S_1 , which is 15.7 cm long and has an inner diameter of 5.9 cm. The winding of S_1 and the leads to it are completely inclosed in a grounded copper shield. A field strength of 74.5 gauss per ampere is obtained.

Detector D includes a small loop antenna, a detector and a two stage amplifier. The radio frequency oscillations from A and B are picked up by D and the audible beat note between them is impressed on the telephone

Fig. 1. Diagram of apparatus.

receiver T . A small mirror attached to T thus vibrates with the frequency of the beat note between A and B . A beam of light from lamp L , is reflected first from a mirror attached to one prong of a 300 cycle electrically driven tuning fork F . It is then reflected from the mirror attached to T and finally falls on a strip of motion picture film in camera E . The film moves downward while both mirrors are arranged to vibrate the beam of light in a horizontal plane. When the fork and heterodyne beat frequencies are about the same the combined motions of the two mirrors thus produce a sort of "photographic" beat as shown in Fig. 2. The frequency of this photographic beat is equal to the difference of the two component frequencies. When the field of S_1 produces magnetostriction in the nickel wire the capacity of C changes and there is a resulting change in the frequency of oscillator B , of the heterodyne note and of the photographic beat.

A time scale is obtained by focusing an image of the filament of an ordinary lamp on one edge of the film. The lamp carries 60 cycle alternating current and the filament vibrates with this frequency when a permanent magnet is brought near. This arrangement is not shown in Fig. 1.

The nickel wire passes through a small bakelite spool on which solenoid S_2 is wound. This solenoid is 0.65 cm in length and 1.58 cm in outside diameter and has 3960 turns. It is connected through a three stage amplifier to a second telephone receiver carrying a mirror. Light reflected from this mirror produces the third trace on the film, in this case a straight line which is broken when the sudden Barkhausen change in magnetization of the nickel wire induces a voltage in S_2 . None of this equipment except S_2 is shown in Fig. 1.

Suitable rheostats are used in series with S_1 to control the magnetizing current. A spiral of fine nickel wire is also connected in series with S_1 . This spiral may be heated by means of a nichrome heating coil which surrounds it, the resulting resistance change producing a slow continuous variation of current over a small range. The rheostats are so adjusted that this continuous change takes place over a range in which the Barkhausen discontinuities are largest.

THEORY OF THE MEASUREMENTS

Let the parallel plate condenser C have capacity C , area A , and plate distance d . Then $C = A/4\pi d$ and if d changes by a small amount δd we get $\delta d = -(A/4\pi C^2)\delta C$ where δC is the corresponding change in C .

Let n_0 be the frequency and C_0 the total capacity of oscillating circuit B . Then if we assume that n_0^2 is inversely proportional to C_0 it may easily be shown that a decrease δC_0 in C_0 will produce an increase δn in n_0 such that

$$\delta C_0 = C_0 \left[1 - \left(\frac{n_0}{n_0 + \delta n} \right)^2 \right] \quad (1)$$

or

$$\delta C_0 = 2C_0 \delta n / n_0 \quad (2)$$

for small changes. The only change in C_0 is that produced by the nickel wire in raising or lowering the upper plate of condenser C . Thus $\delta C_0 = \delta C$ and we get

$$\delta d = -AC_0 \delta n / (2\pi C^2 n_0). \quad (3)$$

In this equation δd is of course the desired change in length of the supporting nickel wire. All the quantities on the right may be easily determined. The area of A of the circular condenser plate as calculated directly from its measured diameter is 3.14 cm². The value of n_0 differs by a negligible amount from the known frequency of the quartz crystal used and may be taken as 1819 kilocycles. The other three quantities are found as follows:

- (1). *Determination of C_0 .*—A wavemeter is used to measure n_0 . Then a known large change in C_0 is produced by means of the calibrated variable condenser C_1 and the frequency $(n_0 + \delta n)$ is again measured. These readings and Eq. (1) give C_0 . The mean of several determinations is $C_0 = 597.4$ cm.
- (2). *Determination of C .* The reading of C_1 is noted when A and B are tuned to the same frequency. Then C is disconnected and B again tuned to the fre-

quency of A by adjusting C_1 . The increase of C_1 required for the retuning gives the value of C to be 41.2 cm.

(3). *Determination of δn .* Let n_A , n_B , and n_F be the frequencies of oscillator A , oscillator B , and the fork F , respectively. For simplicity assume $n_B > n_A$ and $(n_B - n_A) > n_F$. Then $(n_B - n_A)$ is the frequency of the heterodyne beat note between the two radio frequency oscillators and $(n_B - n_A - n_F)$ is the frequency of the photographic beat between this heterodyne note and the fork, as observed on the film. n_A and n_F remain constant. A decrease δd in the length of the nickel wire produces an increase δn in n_B and the frequency of the photographic beat increases to $(n_B - n_A - n_F + \delta n)$. Let $T = 1/(n_B - n_A - n_F)$ and $T' = 1/(n_B - n_A - n_F + \delta n)$ be the periods of the photographic beat before and after the change δd occurs, respectively. Then $\delta n = (T - T')/(TT')$. The periods T and T' are readily obtained from the film by means of the time scale. Obviously some care is necessary to determine whether an observed δn corresponds to an increase or a decrease in the length of the nickel wire.

To get an estimate of the smallest change in length which can be detected assume that $T = 1$ second and that a change in T of 10% can be observed. These conditions are obtained fairly easily. In this case $\delta n = 0.1$ cycle per sec. approximately, and from Eq. (3) $\delta d = 9.7 \times 10^{-9}$ cm. A higher sensitivity is obtained for larger values of T .

It should be mentioned that with this extremely high sensitivity there is always a gradual change in the beat frequency because of unavoidable temperature changes. Vibrations are perhaps an even more serious source of trouble. The condenser C was mounted on sponge rubber, a basement room was chosen for the experiment and records were taken at night; nevertheless seismic disturbances and a temperature drift were always in evidence. The sensitivity could no doubt be considerably increased by further efforts to eliminate these two disturbing factors.

RESULTS

The first specimen was a nickel wire 0.01 cm in diameter and 1.96 cm long. The photographic record showed several Barkhausen discontinuities. A curve was drawn with the period of the photographic beat plotted against time. Since the magnetizing current varied continuously with the time the curve indicated how the length of the wire varied as the field changed continuously. It was found that the smooth course of the curve showed breaks at two of the points where Barkhausen impulses occurred. However, since these breaks were only a little larger than the apparent discontinuities due to experimental error it was felt that the evidence was not entirely conclusive.

Accordingly a new nickel wire 0.002 cm in diameter and 1.98 cm long was prepared by immersing a larger wire for a short time in nitric acid. With a fine wire it was thought that the volume which gives the Barkhausen discontinuity by its magnetization change would be a larger percentage of the whole wire and would thus produce a proportionally larger effect on the gross magnetostriction of the specimen. The results seemed to justify

this idea. The magnetizing field was decreased from a large negative value to zero and then increased to a positive value of 18.6 gauss. A further slow increase to 26.1 gauss was then produced with the hot wire arrangement previously described and the photographic records were taken during this slow increase. There were usually one large Barkhausen impulse and two smaller ones in this region. Fig. 2 shows one of the three photographic records taken of the large impulse. The break at *A* shows the time of arrival of the impulse. The length *BC*, as measured on the time scale *F*, shows the period *T* of the photographic beat before the arrival of the impulse to be (70.2/60) sec. and the length *DE* shows the period *T'* after the impulse to be (10.5/60) sec. Hence $\delta n = (T - T')/(TT') = 4.85$, and from Eq. (3) the change δd in the length of the wire is found to be 4.7×10^{-7} cm. The change in this case was a contraction, showing that the intensity of magnetization had passed through its zero value and was increasing.

Fig. 2. Photographic record of frequency change. The lower record is a continuation of the upper with slight overlapping.

The two other records, taken in the same way, give values of 2.95×10^{-7} cm and 3.6×10^{-7} cm for this quantity. The three determinations thus give an average δd of 3.75×10^{-7} cm. The large impulse did not always occur at exactly the same magnetizing field value and it is probably not to be expected that the three determinations should be in exact agreement. Numerous additional visual observations with this same specimen showed that every Barkhausen impulse heard was invariably accompanied by a simultaneous sudden change in length of the wire.

DISCUSSION OF RESULTS

A qualitative theory of the Barkhausen effect to which the present experiments lend support has previously been proposed.² This theory ascribes the effect to the presence of stresses in the specimen. To be specific,

assume that there is one small volume element in the interior of the nickel specimen which is initially under tension. The two effects of tension on nickel are to produce a decrease in magnetic permeability and a relatively larger increase in the magnetostrictive contraction for a given intensity of magnetization.⁴ Consequently, when the specimen is magnetized the volume element under consideration will contract more than the surrounding material in spite of its abnormally low intensity of magnetization and the initial tension will increase until eventually there is some sort of slipping or rearrangement of the material and the tension is partially or completely released. This release causes a measurable change in length of the specimen only when the cross sectional area of the volume element is an appreciable part of that of the whole specimen. The sudden length change should thus be more prominent in fine wires, as has been observed in the present work. The release of tension also causes a sudden increase in the permeability and the intensity of magnetization of the volume element. Thus we get the Barkhausen effect. This increase in intensity of magnetization will in turn produce a secondary change in the field acting on all other parts of the specimen and in their intensities of magnetization and lengths, but this secondary effect is probably negligibly small.

The following calculation, based on the above conception of the Barkhausen effect, may be considered as a rough approximation. Assume that the volume element which has produced the experimentally observed effects has a length L parallel to the axis of the wire and a uniform cross sectional area a . Let δI be the sudden change in the intensity of magnetization I for the volume element and δL be the accompanying change in L which would result if the element were not restrained by the material around it. The actual length change, which may be identified with the observed δd , may reasonably be taken equal to $\delta L(a/a_0)$, where a_0 is the area of cross section of the whole wire. Ewing's⁵ I vs H curve and an unpublished $\delta L/L$ vs H curve obtained by the present writers together give $\delta L/(L\delta I) = 9.5 \times 10^{-9}$ for hard drawn nickel, the value being taken at a point on the hysteresis loop where $H = 20$ gauss and is increasing. The Barkhausen jumps for which δd was measured were near this point on the hysteresis loop. Then, assuming the magnetic similarity of the three samples of hard drawn nickel involved, the value $\delta L/L\delta I = 9.5 \times 10^{-9}$ may be taken as correct for the volume element considered. Replacing δL by $a_0\delta d/a$, and using the experimentally found values for δd and a_0 , we get $aL\delta I = 1.24 \times 10^{-4}$. Here aL is the volume V of the volume element. The exact value of V cannot be obtained because δI is unknown. However, the maximum value of δI may be taken to be 330, this being the approximate saturation value of I for nickel. The corresponding

⁴ McKeehan states, reference 1, that, "In the case of nickel the resultant orientation of atomic magnetic axes across the axis of tension, which reduces the ease of magnetization along the axis of tension, will increase the magnetostriction (contraction)." Bidwell's experiments, however, (Proc. Roy. Soc. A47, 469, 1890) do not seem to agree with this statement unless large magnetic fields and small tensions are used.

⁵ J. A. Ewing, "Magnetic Induction in Iron," p. 87.

minimum V is 3.76×10^{-7} cc, which is roughly one sixteenth of the total volume of the specimen.

Bozorth and Dillinger⁶ find that V varies over different parts of the hysteresis loop. Their value for the conditions of the present experiment is about 2×10^{-8} cc for annealed nickel, roughly a twentieth of the above found minimum value. However, they assume I to be a complete reversal from a saturation value in one direction to saturation in the other direction. With the same assumption in the present work the discrepancy between the two measurements is reduced to a factor of 10. This is not bad if we consider that the two determinations are widely different in character, that both are somewhat indirect, that the two specimens of nickel differ greatly in size and that one specimen is annealed and the other hard drawn. This last difference alone might account for the discrepancy since it is known that annealing reduces the Barkhausen effect.

The true δI is probably considerably less than the maximum of 330. An estimate may be made as follows. For a Barkhausen discontinuity to occur it is hard to see how the associated volume element could be greater than half the volume of the wire. Taking this value as a maximum for V the equation $V\delta I = 1.24 \times 10^{-4}$ gives $\delta I = 40$ as a minimum. The true δI is probably somewhere between the maximum of 330 and the minimum of 40, V having a corresponding intermediate value. The assumption of a complete reversal of the saturation value of I seems to be unwarranted. The length depends only on the magnitude of I and consequently it is difficult to see how a reversal, which involves no change in magnitude of I , could alone produce any permanent change in length, either the sudden δd of the present work or the gross magnetostriction as usually observed.

THE ISOTOPES OF NITROGEN, MASS 15, AND
OXYGEN, MASS 18 AND 17, AND
THEIR ABUNDANCES

BY S. MEIRING NAUDÉ

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received June 9, 1930)

ABSTRACT

I. The isotopes of nitrogen and oxygen.—The absorption spectrum of the NO γ bands, in particular that of the (0, 0) band at $\lambda 2269$, the (1, 0) band at $\lambda 2154$ and of the (2, 0) band at $\lambda 2052$ was studied in search of isotopes of nitrogen and in order to verify the recently discovered isotopes of oxygen of mass 18 and 17.

A hydrogen continuous source was constructed which could be operated by means of a 5 K.W. transformer which gave 0.5–0.75 amps. through the secondary. It was shown that the silvering of the capillary tube joining the electrodes acts as a catalyzing agent which accelerates the recombination of the hydrogen atoms to molecules thus increasing the intensity of the continuous spectrum. Owing to a chemical change in the fused quartz window on the hydrogen source which leaves the quartz coloured to a violet tint if light of shorter wave-length than $\lambda 1850$ falls on it, the intensity of the continuous spectrum below $\lambda 2300$ is reduced considerably. This was overcome by using a crystal quartz window which did not show this effect. The photographic plates were sensitized with vaseline.

A glass tube 92 cm long and 5 cm in diameter with quartz windows sealed onto either end was used as an absorption tube. NO was prepared by dropping a solution of NaNO_2 into FeSO_4 and H_2SO_4 .

Band heads were observed in all three bands investigated corresponding to the calculated heads for the four kinds of molecules $\text{N}^{14}\text{O}^{16}$, $\text{N}^{15}\text{O}^{16}$, $\text{N}^{14}\text{O}^{18}$ and $\text{N}^{14}\text{O}^{17}$, the maximum deviation of the observed wave-lengths from the calculated values being 0.035A. The results obtained therefore provide new evidence for the existence of a nitrogen isotope of mass 15 and verifies the existence of the oxygen isotopes of mass 18 and 17.

II. The relative abundance of O^{16} and O^{18} .—From the atmospheric bands of oxygen Babcock obtained the relative abundance of O^{16} and O^{18} to be 1250 with a probable error of 25 percent. $(\text{O}^{16})_2$ is symmetric whereas $\text{O}^{16}\text{O}^{18}$ is not. This may give different absorption coefficients for the two molecules. This difficulty disappears in NO. By comparing the pressures of NO in the absorption tube at which the (1, 0) P_1 $\text{N}^{14}\text{O}^{16}$ head could be made to have the same intensity as the P_1 $\text{N}^{14}\text{O}^{18}$ head the relative abundance of O^{16} and O^{18} was found to be 1075 ± 110 .

The relative abundance of N^{14} and N^{15} .—Because in the (1, 0) band the P_1 $\text{N}^{15}\text{O}^{16}$ head has the same intensity as the head Q_1 $\text{N}^{14}\text{O}^{18}$ head, the relative abundance of the N^{15} and O^{18} isotopes is inversely proportional to the relative intensity of the P_1 and Q_1 $\text{N}^{14}\text{O}^{16}$ heads. This relative intensity was found to be 0.65 ± 0.1 . The relative abundance of N^{14} and N^{15} is therefore 1075×0.65 or 700 ± 140 .

From the relative abundance of O^{16} and O^{18} , and O^{16} and O^{17} the mass of the O^{16} isotope was calculated to be 15.9980 ± 0.0002 if the atomic weight of the mixture of isotopes was taken to be 16.0000. Aston defines the mass of the O^{16} isotope as 16.000 and consequently his atomic weights are higher than the corresponding chemical atomic weights. The chemical atomic weights and Aston's should agree if we correct the O^{16} isotope to an atomic weight of 15.9980 ± 0.0002 , that is by 1.25 parts in 10000.

The mass of the N^{14} isotope was calculated to be 14.0069 ± 0.0012 which is in close agreement with Aston's corrected value of 14.0063 ± 0.0029 .

THE search for isotopes, especially among the lighter elements is important,¹ because, as is now generally believed,² any theory of nuclear structure will have to account for the existence or non-existence of all possible atomic species as well as for the regularities³ which exist among the different known isotopes. The occurrence of a certain isotope provides evidence that the corresponding configuration of electrons and protons in the nucleus must be stable. The discovery of the oxygen isotopes of mass 18⁴ and 17⁵ by Giauque and Johnston, and of the carbon isotope of mass 13 by King and Birge^{6,7} throws new light on the stability of atoms having the configurations corresponding to these atomic weights.

Recently the author⁸ reported that evidence had been found from the absorption spectrum of NO of the existence of the four kinds of molecules N¹⁴O¹⁶, N¹⁴O¹⁸, N¹⁴O¹⁷ and N¹⁵O¹⁶, thus not only verifying the existence of the oxygen isotopes of mass 18 and 17 but also proving the existence of an isotope of nitrogen of mass 15. In the meantime more evidence has been found for the existence of these isotopes. The relative abundance of the isotopic species of an element is considered to be a measure of the relative stability of the different atomic configurations constituting the isotopes. Therefore special care has also been taken to find as accurately as possible the relative abundance of the O¹⁸ and N¹⁵ isotopes with respect to O¹⁶ and N¹⁴ respectively.

Part I of this paper gives the evidence that has been found for the existence of the isotopes of nitrogen and oxygen, whereas Part II deals with the experiments carried out to find the relative abundance of the isotopes and the conclusions to which the obtained results lead.

PART I. THE ISOTOPES OF NITROGEN AND OXYGEN

Introduction. According to the theory of the isotope effect in band spectra^{9,10} a molecule containing a rarer isotope of one of the atoms con-

¹⁰ In a Symposium of the Faraday Society held September 1929 on Molecular Spectra and Molecular Structure, Birge discusses methods by which the calculation of the rotational effect can be made more accurate. In this work the approximate formula given in Eq. (2) suffices as the analysis of the NO spectrum made use of here contains relatively large probable errors.

stituting the ordinary molecule, gives rise to a displaced band which corresponds exactly to that which originates from the ordinary molecules. The position of the displaced isotopic band can be calculated accurately by taking into account firstly, the displacement due to vibration:¹¹

$$\nu_2^v - \nu_1^v = (\rho - 1) [\omega_e'(v' + \frac{1}{2}) - \omega_e''(v'' + \frac{1}{2})] - (\rho^2 - 1) [\omega_e'x'(v' + \frac{1}{2})^2 - \omega_e''x''(v'' + \frac{1}{2})^2] \quad (1)$$

and secondly, the displacement due to rotation:

$$\nu_2^r - \nu_1^r = (\rho^2 - 1)\nu_1^r \quad (2)$$

where ν_1 refers to the ordinary molecule $N^{14}O^{16}$ and ν_2 to the isotopic molecule, e.g., $N^{15}O^{16}$, $\rho^2 = (\mu_1/\mu_2)$ where $\mu_1 = 1/M_1 + 1/M_2$ and $\mu_2 = 1/M_1 + 1/M_2'$, M_1 being the mass of the atom which is common to both molecules, and M_2' being the mass of the rarer of the isotopic species M_2 and M_2' , and where ω_e' , $\omega_e'x'$, ω_e'' , $\omega_e''x''$ are vibrational constants in the initial and final states respectively, and v' and v'' are the vibrational quantum numbers in these states.

The absorption spectrum is far superior to the emission spectrum for studying the isotope effect in a gas containing a rare isotope, for by increasing the length of the absorption tube and the pressure of the gas in the tube, the number of molecules in the path of the light can be increased practically indefinitely, and hence also the number of molecules containing a rare isotope. The lower the pressure, the sharper the absorption lines that are obtained. Therefore the absorption tube is chosen as long as possible and then the pressure of the absorbing gas is raised until the expected effect, if present, is observed.

The absorption spectrum of NO, especially the (0, 0) band at $\lambda 2269$, the (1, 0) band at $\lambda 2154$ and the (2, 0) band at $\lambda 2052A$, that belong to the γ system which is degraded towards the violet, offers a good opportunity for studying the isotope effect. This system of NO has been analyzed partly by Frl. M. Guillery¹² and partly by R. Schmid.¹³ Schmid worked on the (0, 0) and (1, 0) bands mentioned. The γ system of NO has a $^2\Pi$ lower level and a $^2\Sigma$ upper level. The separation of the $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$ levels has been found to be 124.4 cm^{-1} . Because the $^2\Sigma$ level is single, every band will exist of a doublet, each having a Q and a P head.¹⁴ Of the (1, 0) band Schmid¹³ was able to measure only the Q_1 heads. The position of the P_1 heads could, however, be calculated with the help of the relation:

$$Q_1(J+1) - \Delta F'(J) = P_1(J) \quad (3)$$

¹¹ The notation used here is in accordance with the report of Prof. Mulliken to be published in the Phys. Rev. Cf. also R. S. Mulliken, Reviews of Modern Physics 2, 60 (1930).

¹² Frl. M. Guillery, Zeits. f. Physik 42, 121 (1927).

¹³ R. Schmid, Zeits. f. Physik 49, 428 (1928).

¹⁴ To avoid confusion the older notation for the heads according to Schmid is used here. The more recent nomenclature of these band heads is given by R. S. Mulliken, Phys. Rev. 32, 413 (1928).

given by him for the final state. This calculation gives 46391.3 cm^{-1} for the wave-number of the P_1 head which agrees with the measurements made in the course of the present work. The position of the P_1 and Q_1 heads of the (2, 0) band were calculated to be 48708.6 and 48736.1 cm^{-1} respectively. The vibrational constants ω_e , $\omega_e x$, used in computing the vibrational isotopic shift of the band heads, were calculated from the ω_0 and $\omega_0 x$ given by Birge:¹⁵ $\omega_e = \omega_0 + \omega_0 x$ and $\omega_e x = \omega_0 x$. The values thus found were $\omega_e' = 2365$, $\omega_e'' = 1902.19$, $\omega_e' x' = 13$, $\omega_e'' x'' = 13.88$. The calculated shifts with the corresponding wave-lengths are given in columns 4 and 5 of Table I.

The continuous source. As continuous light source a hydrogen lamp was constructed of Pyrex glass according to Bay and Steiner.¹⁶ The source could be operated with a 5 K.W. transformer giving from 0.5 to 0.75 ampere through the secondary. This gave a very intense continuous spectrum. The source was provided with a quartz window at either end. The second window allowed one to sight through the hydrogen source, thus greatly facilitating the lining up of the source, the absorption tube and the spectrograph, which is very important in the case of a long absorption tube, for in this way the maximum intensity can be obtained.

Some experiments were carried out to find out what function was fulfilled by the silvering of the capillary tube which joins the electrodes and in which the discharge takes place, as no conclusions were made in this respect by Gehrcke and Lau¹⁷ who first describe its use. It was found that, when the capillary tube was not silvered the discharge was distinctly red due to the H_α line becoming very prominent. On the other hand, when it was silvered the secondary and also the continuous spectrum of hydrogen which is emitted by the hydrogen molecule,¹⁸ became much stronger, H_α being reduced to about the same intensity as that of the secondary spectrum. The evidence thus points to the mechanism of the silvering being to catalyze the recombination of hydrogen atoms into which the molecules dissociate on giving out the continuous spectrum back to molecules, thus strengthening the secondary spectrum and hence also the continuous spectrum.

As is well known¹⁶ the observed intensity of the hydrogen continuous spectrum falls off rapidly below $\lambda 2400\text{A}$. Experiments were carried out to determine the cause of this phenomenon. It was noticed that a fused quartz window sealed onto the hydrogen tube gave a very strong fluorescence¹⁹ when the tube was in operation. After a window had been in use for about a week, it was replaced by a new one. It was then noticed that the used one had been discoloured to a violet tint, the pattern in it being the same as the one that was seen in fluorescence while the tube was in use. The hydrogen tube was now refilled and sealed off. Two absorption pictures were taken on the

same photographic plate, the first with the used quartz window and the second with an unused window in the light path. It was found that the used window absorbed very strongly in the region below $\lambda 2400\text{\AA}$. The used quartz window had to be ground down to about half the original thickness before the violet tint was removed. It is not known what the cause of this colouring is, but it seems likely that the SiO_2 constituting the quartz dissociates, giving free silicon. The wave-length causing this fluorescence must be shorter than $\lambda 1850$, the shortest wave-length transmitted by quartz, because the fused quartz windows used on the absorption tube showed no fluorescence and when the windows were removed after being in use for six months, no violet colouring could be observed. A crystal quartz window was ground and polished and used to replace the fused quartz window on the hydrogen source. The fluorescence in this window was distinctly less conspicuous and the intensity of the continuous spectrum obtained was much better. This window showed no violet colouring even after being in use for three months. It is therefore advisable to use crystal quartz instead of fused quartz windows on the hydrogen source for work in the far ultraviolet.

Procedure. A tube 92 cm long and 5 cm in diameter and with two quartz windows sealed onto either end served as absorption tube. The NO gas was prepared by dropping NaNO_2 into a solution of H_2SO_4 and FeSO_4 . The end of the dropping funnel was well below the surface of the liquid so that all the NO_2 formed could be reduced to NO by the FeSO_4 . The NO gas was left over the FeSO_4 for about a day so that the gas obtained was practically free from NO_2 . The NO gas was dried by passing it through a tube containing P_2O_5 . The pressure of the gas could be determined by means of a McLeod gauge.

An E1 Hilger spectrograph was used which had a dispersion varying from 1 mm = 1.9A at $\lambda 2269$ to 1.3A at $\lambda 2052$. The time of exposure varied from six to twelve hours. The best pictures were taken with 2 cm pressure of NO in the absorption tube. Speedway and Eastman 40 plates were used. The copper arc lines measured by Mitra²⁰ and corrected by Shenstone²¹ were used as comparison spectrum. In the region below $\lambda 2100$ the copper lines as given by Sommer²² are less accurately measured and consequently the measurements on the (2, 0) band are less accurate.

The insensitivity of the photographic plate in this region, $\lambda 2300$ to 2000\AA , was overcome by using a solution of five grams of vaseline²³ in half a liter of petroleum ether²⁴ as sensitizer according to Beach.²⁵ The solution was prepared and kept in a glass bottle. Before taking an exposure the photo-

graphic plate was dipped into the solution which had been previously poured into a flat dish. On taking it out an oscillatory movement was carried out in order to dry it in such a way that the film of vaseline formed on the surface of the plate after the petroleum ether had evaporated, should be as even as possible. An even film of vaseline was essential especially where a comparison was made between the intensity of two photographs on the same plate (as described in Part II), since the thickness of the film of vaseline determines the intensity obtained.

The plate was then inserted into the holder and the photograph taken in the ordinary way. Before the plate was developed, the vaseline was removed by rubbing its surface with cottonwool which had been soaked in acetone. The plate was then developed as usual.

Results. In all three bands bandheads are observed corresponding to the four types of molecules $N^{14}O^{16}$, $N^{15}O^{16}$, $N^{14}O^{18}$ and $N^{14}O^{17}$ except in the (0, 0) band where, owing to the smallness of shift and the proximity of the $N^{15}O^{16}$ head, the much weaker $N^{14}O^{17}$ head is not observed.

The results are tabulated in Table I being the average of the measurements on five different plates taken at different pressures.

TABLE I.

Band		Nomenclature wave-length and wave-number of $N^{14}O^{16}$ head	Type of molecule containing an isotope	Calculated shift $\nu_2 - \nu_1$ in cm^{-1}	Calculated wave-length in Å	Observed wave-length in Å

In the preliminary publication⁸ mention was made of faint absorption bands appearing beyond the isotopic heads in the (1, 0) band, whose positions seemed to agree with the values calculated for a possible $N^{16}O^{16}$ head. This point has been the subject of further research. When the focus of the spectrograph was shifted so as to include the (2, 0) band, it was found that the β bands of NO^{26} which originate from the same $^2\Pi$ ground state as the γ bands, but have an upper $^2\Pi$ level different from the $^2\Sigma$ upper level of the

²⁶ F. A. Jenkins, H. A. Barton and R. S. Mulliken, Phys. Rev. 30, 150 (1927).

γ bands, also appear in absorption although very weakly. Now it happens that the heads of the *R* and *P* branches of the (1, 0) β band fall at $\lambda 2153.45$ and 2153.68\AA and thus on top of the (1, 0) γ band. Consequently these heads do not interfere with the isotopic bandheads. Because the β system is degraded towards the red, its rotational fine structure appears beyond the isotopic heads. The position of these rotational lines can be calculated from the relation

$$F = \text{const} + Aj + Bj^2 + Cj^3 + Dj^4$$

given by Jenkins, Barton and Mulliken.²⁶ All the observed absorption lines beyond the heads of the isotopic molecules could be accounted for in this way. The isotope N^{16} does therefore not exist (unless it is less abundant

Fig. 1. The expected appearance of the band-heads of the (1, 0) band are sketched. The types of molecules giving these band-heads are given on the upper side of the figure and on the lower side the corresponding wave-lengths of the heads are given. The line on the lower side of the figure joins the Q_1 heads formed by the different types of molecules, whereas the upper line joins the corresponding P_1 heads.

Fig. 2. An enlargement of the observed appearance of the (1, 0) band. The positions of the band heads are indicated by lines which connect the heads to the corresponding heads in Fig. 1.

than O^{17}) especially since the (2, 0) band shows definitely no trace of the N^{16} isotope. The evidence the (1, 0) band gives for the other isotopes is, however, not effected by these faint absorption lines since the intensity of the isotopic heads is much greater than the rotational fine structure of the (1, 0) β band.

Because the P_1 and Q_1 heads of the (1, 0) band are separated by 27.3 cm^{-1} and the smallest displacement, namely that of the Q_1 head due to the $\text{N}^{14}\text{O}^{17}$ molecule is -35.193 cm^{-1} , one expects the six heads due to $\text{N}^{14}\text{O}^{17}$, $\text{N}^{15}\text{O}^{16}$ and $\text{N}^{14}\text{O}^{18}$ all to fall beyond the $\text{N}^{14}\text{O}^{16}$ P_1 head and to be observable as far as they do not overlap one another. In Fig. 1 a sketch is given of the expected appearance of the bandheads. In Fig. 2 a photograph (enlarged eight times) of the actual appearance of the (1, 0) band is reproduced. This photograph was taken with a pressure of 2 cm of NO in the 92 cm absorption tube, the time of exposure being ten hours.

Between the Q_1 $\text{N}^{14}\text{O}^{17}$ and $\text{N}^{15}\text{O}^{16}$ heads a faint absorption line is seen which could be shown to be due to the overlapping of three lines of the rotational structure belonging to the Q_1 $\text{N}^{15}\text{O}^{16}$, and $\text{N}^{14}\text{O}^{18}$ heads and the P_1 $\text{N}^{15}\text{O}^{16}$ head. The P_1 $\text{N}^{14}\text{O}^{17}$ head is not visible in this picture but in pictures taken at higher pressures one is able to observe and measure it accurately.

The separation of the P_1 and Q_1 heads in the (2, 0) band is 27.5 cm^{-1} . The displacement of the Q_1 $\text{N}^{14}\text{O}^{17}$ head is calculated to be 66.401 cm^{-1} and will therefore fall beyond the P_1 $\text{N}^{14}\text{O}^{16}$ head. All the isotopic heads are therefore expected to fall beyond the P_1 head. As can be seen from the calculated positions of these heads in column 5 of Table I, they are widely separated and can therefore be measured more accurately. The increased insensitivity of the photographic plate, however, makes a reproduction of the obtained pictures impossible.

The fine structure of the isotopic bands could also be measured when the overlapping was not too much. This corresponded very closely with the rotational fine structure of the main heads, so that it provides further decisive evidence that these heads must be due to the isotopic molecules.

To be absolutely sure that these bands might not perhaps be due to some other molecule, e.g. $(\text{NO})_2$, the absorption tube was replaced by a tube 1.2 cm in length and filled up to 75 cm pressure with NO. The light passing through this tube has to traverse about the same number of molecules of NO as in the case of the 92 cm tube with 1 cm pressure. If $(\text{NO})_2$ molecules were present their concentration should increase with the square of the pressure and the path being 75 times shorter, one would expect the effect due to these molecules to be 75 times as intense. The absorption of the isotope heads observed is quite similar to that obtained with the 92 cm tube, except that they are a little more diffuse, as one might expect owing to the high pressure. The measured shift agrees accurately with the above results.

This investigation therefore definitely proves the existence of an isotope of nitrogen of mass 15 and verifies the existence of the recently discovered isotopes of oxygen of mass 17 and 18.

PART II. THE ABUNDANCE OF O^{18} AND N^{15}

The relative abundance of O^{16} and O^{18} . The abundance of the oxygen isotope of mass 18 has been determined by Babcock²⁷ from the atmospheric

²⁷ H. D. Babcock, Proc. Nat. Acad. Sci. 15, 471 (1929); Phys. Rev. 34, 540 (1929).

bands of oxygen. Babcock took an absorption picture of the atmospheric bands using the sun as continuous light source and the oxygen in the atmosphere as his absorbing medium. In this way the heads of the displaced bands due to the $O^{16}O^{18}$ molecule could be photographed. On the same plate he took an absorption picture of the corresponding main bands due to $(O^{16})_2$ using a certain length of air path in the laboratory for the absorption. When the isotopic heads in the former appeared to him to be of the same intensity as the main heads in the latter picture, he concluded that the abundance of the molecules giving these bands should be inversely proportional to the number of oxygen molecules traversed in each case. The latter could be calculated from the known path lengths. In this way a relative abundance of one O^{18} isotope in every 1250 O^{16} was obtained as the weighted mean of 1175 and 1350.

The molecule $(O^{16})_2$ is symmetric whereas $O^{16}O^{18}$ is unsymmetric. These molecules may have different absorption coefficients which would affect the results obtained for the relative abundance. This difficulty disappears in the case of NO, for both $N^{14}O^{16}$ and $N^{14}O^{18}$ are unsymmetric. A redetermination of the abundance of O^{18} therefore seemed desirable.

The pressure of NO in the absorption tube could be varied thus giving different numbers of molecules in the light path, and could be measured accurately by means of a McLeod gauge. The pictures were taken on the same photographic plate, 5 mm apart, so that the condition of sensitizing and developing were exactly the same. The two pictures could be taken under the same experimental conditions and special care was taken to get the continuous background of the pictures of the same intensity.

The (1, 0) band is the best to apply this procedure to, because the intensity of the plate is still favourable and the displacement of the isotope heads is fairly large. The only displaced head to which the method can, however, be applied with certainty is the $N^{14}O^{18}$ head at $\lambda 2157.98$ corresponding to the P_1 head of $N^{14}O^{16}$ $\lambda 2154.90$. This head is displaced the farthest and consequently there is no overlapping of the fine structure of the less displaced isotopic heads. The fine structure of the (1, 0) β band mentioned above is so weak that it does not affect the accuracy with which the intensity of the displaced isotope head can be estimated.

The first pictures taken showed that the higher pressure caused the isotopic head to appear much broader than expected. Pressure broadening according to Lorentz²⁸ was at once suspected to be the cause. Two pictures were taken on the same plate, one with only 2.1 cm pressure of NO in the absorption tube, the other with the 2.1 cm of NO left unchanged but with 44 cm pressure of N_2 added, see Fig. 3. Since the N_2 has no absorption bands in this region it can only have the effect of pressure broadening according to Lorentz. A large number of investigators²⁹ have done work on the pressure

²⁸ H. A. Lorentz, Proc. Amsterdam 8, 501 (1906). For a discussion of this phenomenon according to the wave mechanics cf. J. Frenkel, Zeits. f. Physik 59, 198 (1930).

²⁹ Cf. W. Schütz, Zeits. f. Physik 45, 30 (1927) and the literature given there.

broadening in the case of atoms, and Teves³⁰ has extended this work to bands. The pressure in the absorption tube was therefore regulated as follows: If a pressure ratio of 1 to 1000, for instance, was desired, the tube was filled to 5 cm with NO and 65 cm of N₂ added. After an exposure with this pressure was finished, the pressure in the tube was changed to 0.005 cm of NO and 70 cm of N₂, and another picture taken on the same photographic plate. In both cases therefore the total pressure was the same, viz. 70 cms, and a large excess of N₂ was present. N₂ was chosen, chiefly because it has no absorption bands above $\lambda 1520\text{\AA}$ and also because it has about the same molecular radius as NO³¹, the latter factor influencing the broadening according to Lorentz and Frenkel. It was absolutely necessary to have N₂

Fig. 3. (a) Absorption picture with 2.1 cm NO pressure. (b) Absorption picture with 2.1 cm NO+44 cm N₂ pressure. A comparison shows that in (b) every rotational line is broadened so much that the absorption becomes complete.

free from all traces of oxygen otherwise NO₂ would be formed in the absorption tube and this molecule gives a continuous absorption in the region in question. Pure N₂ was obtained by heating sodium azide in a flask from which all the air had been exhausted beforehand. The gas was then dried in a tube containing P₂O₅. Pictures were taken with pressure ratios varying between 1 in 1800 and 1 in 500. Definite differences in the intensity of the absorption of the main and isotopic heads were found for all ratios outside 1 in 990 and 1 in 1160. Within this region ten photographs were taken at different pressure ratios, but, as it is difficult to decide definitely about their intensities, an average is taken over all ten values giving as result a relative abundance

³⁰ M. C. Teves, *Zeits. f. Physik* **48**, 244 (1928).

³¹ P. M. Morse, *Phys. Rev.* **34**, 57 (1929).

of O^{18} of one in every 1076 O^{16} atoms. Taking the mean of the two extreme ratios where definite differences of the same amount could be observed in the intensities a ratio 1/1075 is found for the abundance. Although the first calculation gives a probable error of only three percent, the maximum error is given as ten percent, as systematic errors might occur in the method used. The abundance ratio of O^{16} to O^{18} is therefore given as 1075 ± 110 .

After obtaining the above result two comparison pictures were taken with helium instead of N_2 to make sure that no resonance effect between NO and N_2 was present. The pictures indicated that the given abundance ratio was correct.

The result differs by about 14 percent from that given by Babcock, but as Birge³² gives a probable error of 25 percent for Babcock's values this deviation does not seem too large. Further, Babcock compares the absorption of the oxygen in the laboratory and hence at atmospheric pressure with the oxygen in the atmosphere where the pressure varies exponentially to zero. Hence the pressure broadening which, as pointed out above, is very great, is much more effective in the first case where all the oxygen is at atmospheric pressure than in the second case where only the oxygen near the ground is at atmospheric pressure. This would give a result which would differ from the one obtained with the same pressure in both cases in the sense of the result found here.

Babcock finds the relative abundance of O^{18} and O^{17} to be eight to one. If a maximum error of ten percent is allowed for this value and the relative abundance of O^{16} and O^{18} is assumed to be 1075 ± 110 as found here, the relative abundance of O^{16} and O^{17} becomes 8600 ± 1750 .

The relative abundance of N^{14} and N^{15} . As stated above the overlapping of the fine structure due to the $N^{14}O^{18}$ molecule, made it impossible to determine the abundance of the $N^{15}O^{16}$ molecule in the same way. Here the circumstance that the $Q_1N^{14}O^{18}$ and $P_1N^{15}O^{16}$ heads lying close together are of the same intensity was made use of. At very low pressures practically no fine structure of the isotopic heads is present and therefore the conclusions following this observation are rigid. It was further noticed that the $P_1N^{15}O^{16}$ head was more intense than the $Q_1N^{15}O^{16}$ head. This resulted from the fact that the main $P_1N^{14}O^{16}$ head was less strongly absorbed than the corresponding Q_1 head. The ratio of the main P_1 and Q_1 heads could easily be determined by taking different pressures in the absorption tube and observing at which pressures the heads had the same intensity. The ratio of these pressures was found to be 0.65 ± 0.1 and this is evidently the intensity ratio of the main heads, the P_1 head being less intense. This result could also be verified by taking microphotometer curves of the heads with a Moll apparatus and averaging the area under each of the heads. This result agreed accurately with the above result. The fact that the $Q_1N^{14}O^{18}$ and $P_1N^{15}O^{16}$ heads are equally intense can therefore only be ascribed to the fact that the $N^{14}O^{18}$ must be less

³² R. T. Birge, Phys. Rev. Suppl. 1, 69 (1929).

abundant than the $N^{15}O^{16}$ in the same ratio as the Q_1 head is stronger than the P_1 head.

This result therefore gives us as relative abundance of $N^{14}O^{18}$ and $N^{15}O^{16}$ molecules the ratio 0.65 ± 0.1 and hence as the relative abundance of N^{14} and N^{15} the ratio 1075×0.65 or 700 ± 140 . In this case the maximum error is given as 20 percent, since the ratio 0.65 may be affected as much as ten percent by systematic errors.

Discussion. The existence of the O^{18} and O^{17} isotopes seems to be quite certain. This, however, affects Aston's³³ atomic weights determined by means of the mass spectrograph with respect to the chemical atomic weights.³⁴ Aston assumes the atomic weight of the O^{16} isotope to be 16.0000, whereas the chemical method defines the average atomic weight of the O^{16} , O^{17} and O^{18} isotopes as 16.0000. The actual atomic weight of the O^{16} isotope can now be calculated by making use of the relative abundance determined above. The atomic weight of the O^{16} isotope can be computed from the following relation:

$$1074 \times 8x + 8 \times 18 + 17 = (1075 \times 8 + 1)16.0000 \quad (4)$$

from which we get $x = 15.9980 \pm 0.0002$. We see therefore, that although the maximum error in the relative abundance of the oxygen isotopes is very large, the value of the atomic weight of the O^{16} is little affected. It is easily seen that it makes no difference in the result whether 18 or 17.991,³⁵ as recently found by Mecke and Wurm to be the atomic weight of O^{18} , is used. If the chemical atomic weight 16.0000 is our standard, Aston should use 15.9980 ± 0.0002 as the atomic weight of the O^{16} isotope, if he expects to obtain an agreement between his values and those obtained by chemical methods. This change in value of the O^{16} isotope used as standard by Aston corresponds to a change of 1.25 ± 0.13 in 10000. This does not mean that Aston's determinations of the atomic weights are less accurate than 1 in 10000 as given by himself, but just gives the amount by which all his values have to be corrected in order to allow a comparison with the values obtained by chemical methods.

We can now proceed to correct Aston's values by 1.25 ± 0.13 in 10000. In Table II the corrected values of Aston are compared with the chemical determinations. The elements chosen are those which have no isotopes as far as we know, or which have rare isotopes, as these are the only cases where a direct comparison is possible.

A comparison of columns 1 and 3 reveals a number of interesting points. In the case of hydrogen a correction of Aston's value makes the agreement worse, but the corrected value can be made to agree with the chemical value by assuming an error of 0.00011 which is well within the maximum error allowed for.

TABLE II. *Atomic weights.*³⁶

Atom	Chemical method	Aston's mass spectrograph	Aston's values corrected by 1.25 in 10000
H	1.00777 ± 0.00002	1.00778 ± 0.00015	1.00766 ± 0.00016
He	4.0018 ± .0003	4.00216 ± .0004	4.00166 ± .00045
C	12.0025 ± .00019	12.0036 ± .0012	12.0021 ± .0014
N	14.0083 ± .0008	14.008 ± .0028	14.0063 ± .0030
O	16.0000 ± .0000	16.0000 ± .0000	15.9980 ± .0002
F	19.00	19.0000 ± .0019	18.9976 ± .0021
P	31.027	30.9825 ± .0046	30.9786 ± .0050
As	74.96	74.934 ± .010	74.925 ± .011
I	126.93	126.932 ± .025	126.916 ± .027

In the case of He the corrected value agrees to 1 in 30000 with the chemical value 4.0018. This correction therefore does away with a very bad discrepancy between Aston's values and the chemical values. Further, as pointed out by Birge³⁷ this value agrees accurately with Eddington's³⁸ calculated value for an ideal rigid nucleus. This agreement might be due to chance as the value still has a large maximum error and hence it cannot be assumed from this that the helium atom really has a rigid nucleus.

Birge and King have recently discovered an isotope of carbon of mass 13. One would therefore expect the chemical atomic weight to be higher than that found by Aston. The reverse is the case, however. If Aston's value is corrected one obtains a value of 12.0021 which is in close agreement with the chemical value 12.0025 and still allows for the presence of the isotope C¹³. From these values the calculated abundance of the C¹³ isotope is 1 in 2500 but this seems to contradict Birge's⁷ results according to which the C¹³ isotope should be more abundant relative to C¹² than the N¹⁵ relative to N¹⁴, but the given atomic weights still have a large probable error which may account for this discrepancy.

In the case of nitrogen the abundance of the N¹⁵ has been determined as 1 in 700 ± 140 N¹⁴ isotopes. From this we can determine what the expected atomic weight of the N¹⁴ isotope should be, for

$$700x + 15 = 701 \times 14.0083 \pm 0.0008 \quad (5)$$

or

$$x = 14.0069 \pm 0.0012.$$

This value agrees with Aston's corrected determination 14.0063 to within 1 in 20000.

For F, P and As the chemical values are given with less accuracy, but a comparison of Aston's corrected value of P with the chemical value leads

³⁶ Most of the values with their probable errors given in the first column are taken from the excellent discussion by R. T. Birge, *Phys. Rev. Supplement* **1**, 18 (1929). The values in column 2 with their maximum errors are obtained from Aston's paper, *Proc. Roy. Soc.* **115A**, 487 (1927). The chemical values for F, P, As and I are taken from the Second Report of the International Committee on Chemical Elements, *J. Am. Chem. Soc.* **47**, 597 (1925) and the German Committee, *Berichte* **62**, 1 (1929).

³⁷ R. T. Birge, *Phys. Rev.* **35**, 1015 (1930).

³⁸ A. S. Eddington, *Proc. Roy. Soc.* **A126**, 696 (1930).

one to suspect the presence of heavier isotopes of P in small quantities. Although less certain, the same seems to be indicated by the corresponding values for F and As.

Until 1928 the German Committee³⁹ gave the atomic weight of I as 126.92 and Birge⁴⁰ finds as weighted average of Clark's values 126.926. This indicates that the real chemical value for I may still be on the lower side of 126.932—the value that is now accepted—and such a value will be in better agreement with Aston's corrected value 126.916.

Although it is difficult to draw definite conclusions from the above, it is quite clear that the sooner an agreement is reached by chemists and physicists as to the value which should be used as standard of atomic weight, the less confusion will exist as to the most accurate atomic weights.

Mr. F. Bueso-Sanlehi started this work but had to leave before obtaining any definite results. I wish to thank Professor R. S. Mulliken who suggested the search for isotopes in these NO bands and also wish to thank him and Dr. A. Christy for their helpful suggestions and Professor H. B. Lemon for allowing me the use of the apparatus in his laboratory.

THE MARGULES METHOD OF MEASURING VISCOSITIES
MODIFIED TO GIVE ABSOLUTE VALUES

BY HOWARD R. LILLIE

CORNING GLASS WORKS, CORNING, NEW YORK

(Received May 28, 1930)

ABSTRACT

Measurement of absolute viscosities. A method for determining absolute viscosities in a Margules rotating cylinder type viscometer, without the aid of calibrating liquids of known viscosities, is described. This method involves the determination of true viscosity by extrapolating apparent viscosities for several lengths of inside cylinder to that viscosity corresponding to infinite length. By this method the viscosity of the commercial castor oil used is found to be 9.99 poises at 20°C, and 4.61 poises at 30°C, as compared with 9.86 and 4.51 poises quoted in the Smithsonian Tables for pure oil at corresponding temperatures.

End corrections. The additional length to be applied to the measured length to correct for finite dimensions is computed for several inside cylinders or spindles. When the radius of the outer containing cylinder is 3.2 cm, and the ends of the spindle are 1.5 cm from the upper and lower boundaries of the liquid, the corrections for spindle radii of 0.556 cm and 0.477 cm are found to be 0.62 cm and 0.52 cm respectively as long as the length of the spindle is 5 cm or greater. Accordingly, the end correction is apparently proportional to the 1.18 power of spindle radius.

Constancy of calibrating factor. Comparisons are also made between relative viscosities measured by this method and those for the same liquids measured by capillary flow. Results indicate that within experimental error these relative values are the same by both methods, for viscosities between 5 and 3500 poises, showing that the calibrating factor of the concentric cylinder system is constant over this range of viscosities.

IN A previous paper,¹ the apparatus and method were described for measuring viscosities of molten glasses (10^2 to 10^7 poises) by the use of concentric cylinders. A simple way of determining the effect of the use of cylinders of finite length was also described. However, since this determination was made for only one viscosity—that of castor oil at room temperature—the question remained as to whether one can assume that the calibrating factor is entirely independent of viscosity when the ends of the cylinders are present. Measurements were accordingly undertaken with the object of comparing the relative viscosities of two liquids differing quite widely in this property, as found by the concentric cylinders and as given by the method of capillary flow, for which a constant calibrating factor is more generally accepted.

In a majority of cases, investigators of glass viscosities² have found, by more or less rigorous calibration with standard liquids, that the calibrating factor is apparently independent of viscosity. On the other hand, in an

investigation of the viscosities of soda-lime glasses over a large field of compositions, Washburn³ found that his factor existing between force per unit shear and viscosity apparently varied by a factor of about three over the range of viscosities dealt with. Comparisons made by others have shown that agreement between their results and those of Washburn can be reached only if his calibrating factor be changed to a constant or their own made variable.

Since in any rotation method the torque is simply proportional to the viscosity and to the velocity gradient at the very surface of the cylinder upon which the torque is exerted, a variation in the factor connecting torque and viscosity for a given total relative angular motion between the two cylinders, would indicate that the velocity gradient at the surface of the cylinder is not proportional to the total relative velocity alone. In other words, the velocity distribution would have to depend on viscosity. The result of this would be that if the temperature of a liquid, contained between a stationary cylinder and one rotating with a constant speed, be changed so as to alter its viscosity, some parts of the liquid would be thereby slowed down while others would rotate faster in order to change the velocity gradient to the cylinders' surfaces. This is only conceivable if centrifugal or other forces tending to disturb the regular motion of the liquid have more effect in the less viscous liquid. This may be true in the case of cylinders of finite length.

MEASUREMENT BY THE CONCENTRIC CYLINDER METHOD

Mathematical procedure.

As reported in the previous papers, viscosities have been measured without the aid of actual calibration with standard liquids, simply by determining the magnitude of the "end effect" at some arbitrary viscosity and assuming a constant calibrating factor for all viscosities. The end effect was determined by first finding the apparent viscosity of the liquid, using inside cylinders or spindles of various lengths, by using the formula

$$T = \frac{4\pi\eta\Omega R_1^2 R_2^2 l}{R_2^2 - R_1^2} \quad (1)$$

where T is the torque on the inner cylinder, η the viscosity, Ω the angular velocity of the outer cylinder, R_1 and l the radius and length of the inner cylinder and R_2 the radius of the outer rotating cylinder. These apparent viscosities were then plotted against reciprocals of spindle length and the "true" value of η corresponding to infinite length found by extrapolation. A correction to l was then found for each spindle. This correction is not the same for all lengths of spindles of the same diameter, supposedly because the amount of deformation of the flow surfaces around the body of the spindle depends on the length of the spindle itself.

Some minor changes have been made in the method of computation of apparent viscosity. We have the relations

³ Washburn, Libman and Shelton, Univ. of Illinois, Eng. Expt. Sta., Bull. No. 140 (1924).

$$T = K\theta = \frac{KZD}{2d}$$

and

$$\Omega = \frac{2\pi}{t},$$

where K is the constant of the suspension, determined as described in the previous paper, θ its angular displacement, D the deflection as read on a scale at a distance d from the mirror, Z the correction for straight scale and t the time for one revolution of the containing cylinder. Eq. (1) becomes

$$\frac{KZD}{2d} = \eta \frac{8\pi}{t} (\pi R_1^2 l) \frac{R_2^2}{R_2^2 - R_1^2},$$

or, for apparent viscosity,

$$\eta = \frac{ZDt}{d} \left[\frac{K}{16\pi V} \left(1 - \frac{R_1^2}{R_2^2} \right) \right] \quad (2)$$

where V is the total volume of the spindle. The quantity in the brackets is a constant for any one spindle since a constant value of $R_2 = 3.2$ cm was used during the whole investigation. All apparent viscosities were computed from this equation.

Fig. 1 represents diagrammatically the experimental viscometer used. A water bath is contained in a large cylindrical can placed on the rotating table V of the viscometer frame described previously. This can is surrounded by a galvanized water jacket J , the purpose of which is to maintain an external temperature below that of the bath. The outer cylinder of the measuring viscometer, C , containing the liquid under investigation, is supported at the center of the bath by a hollow pedestal of brass and is closed by a threaded top carrying a small upright tube which extends through the surface of the water bath and allows the inner cylinder or spindle E to hang into the liquid. This spindle is held by a brass connector D upon which is fastened the mirror M , all of which hangs from the calibrated steel wire suspension B . With the exception of spindle No. 53, described later, the two ends of the spindle were 1.50 cm distant from the surface of the oil and the bottom of the container.

The temperature is maintained constant by means of a vapor pressure regulator R constructed as shown. Methyl formate was found to be the most satisfactory liquid for actuating the mercury column. Various temperatures can be obtained by adjusting the pressure of air in the top part of the regulator. The contacts of the regulator are connected in series with a small flashlight dry cell and a telegraphic relay, both of which are fastened to the transite cover piece of the rotating can. This relay makes and breaks the circuit through the heater H consisting of three units of nichrome wire which can be connected in various ways depending on the temperature desired. The current for the heater is supplied through mercury cups at the extreme bottom of the viscometer frame. Circulation of the water bath is maintained

by a small toy electric motor directly connected to the shaft of the stirrer *A*. This stirrer is so built as to take water in from top and bottom and eject it tangentially at the center. Current for the motor is supplied by a large 4 volt storage battery, through brushes acting on rings around the outside of the jacket *J*. It was found necessary to house the motor completely to prevent disturbance of the spindle due to air currents from the armature. At times

Fig. 1. Diagram of apparatus.

when various spindles were being used, one after another, a preheating tube *P* was installed containing some of the same oil as was being used in *C* so as to allow the next spindle to come to temperature before being placed in the central position. Temperatures were measured by means of three copper-constantan thermocouples placed as shown (*TC*) and connected in series through junctions kept at 0°C. A precision potentiometer accurate to less

than 1 microvolt was used for e.m.f. readings. These couples measured the average temperature of the bath to within 0.05°C and were sensitive to changes of less than 0.01°C . Their condition was checked periodically with a standard mercury thermometer to make sure that no short circuits were causing them to be far in error.

Temperature control.

Since all temperature readings made during actual viscosity measurements were for the water bath instead of for the liquid inside the viscometer proper, a few test runs were made to establish the relations between these temperatures. By placing a second set of couples in the center of the oil its temperature could be followed while the bath was cooling, heating, and just after it had come to equilibrium. In this way the following conditions were found:

Heater turned off: temperature lag 2.3°C , time lag 35 min.

Heater turned on: temperature lag 1.3°C , time lag 17 min.

(rate $0.08^{\circ}\text{C}/\text{min.}$)

Length of time after regulator began working, for oil to be

within 0.05°C of bath: 50 min.

within 0.01°C of bath: 70 min.

Accordingly, about two hours were always allowed, after the regulator began to function, before any viscosity readings were made. It was also observed that when the regulator had been in action for some time no periodic fluctuation of temperature in the oil could be detected.

Effective spindle length.

For determining "true" viscosities by extrapolating the apparent values for several spindles of equal radii but various lengths to the value corresponding to infinite length, five spindles of $3/8"$ diameter and five of $7/16"$ diameter were used. Their actual dimensions were:

No.	R_1	l	$1/l$	No.	R_1	l	$1/l$
101	0.4766 cm	10.14 cm	0.0986	106	0.5561 cm	10.22 cm	0.0979
102	.4771	7.61	.1314	107	.5562	7.60	.1315
103	.4769	5.08	.1969	108	.5564	5.12	.1953
104	.4768	3.80	.263	109	.5561	3.82	.262
105	.4770	2.53	.396	110	.5561	2.54	.394
Mean	0.4769			Mean	0.5562		

The observed apparent viscosities found by the use of these spindles (R_2 constant and equal to 3.2 cm) are shown in Table I. The ratios of viscosity at 23.40°C and 28.20°C to that at 19.97°C , as given by each spindle, are also shown. It is quite evident that over this small range of viscosities relative results are independent of the spindle used. A mean of these ratios for the two higher temperatures was accordingly taken, weighting each value according to spindle length, and all the viscosities recomputed back to the basis

TABLE I

Spindle No.	Observed Values						Mean μ	Values read from curve (Fig. 2)	
	19.97°C $\eta = 10.020$		23.40 $\eta = 7.633$		28.20 $\eta = 5.295$			App. η	l'
	App. η	l'	App. η	Ratio	App. η	Ratio

Mean ratios				.7618	.5284				

of 19.97°C. This process gave the points plotted in Fig. 2. Since for a given radius of spindle the relation between apparent viscosity and reciprocal of length appeared to be a linear one for values of l greater than 5 cm, this was assumed to be true and the apparent viscosities as given by the six longest spindles were used for determining the best pair of straight lines intersecting

Fig. 2. Apparent viscosities of castor oil. Spindles 101-110 inclusive. Converted to 19.97°C

at $1/l=0$. In so doing it was discovered that the sum of the deviations become minimum for the two lines separately as well as collectively when the intercept was made at 10.020 poises. The average deviation in this case was about 0.3 percent, using only those spindles of length greater than 5 cm. The curved part of each line was drawn by estimate.

Using the extrapolated intercept as the true viscosity at 19.97°C and the mean ratios shown in Table I for computing the corresponding values at the

two higher temperatures, the following comparison is made with viscosities of pure castor oil as given by the Smithsonian Tables:

Temp.	Observed	Sm. T.
19.97°C	10.020 poises	9.92 poises
23.40	7.633	7.42
28.20	5.295	5.14
$\Delta \log \eta / \Delta 1/T$	297	302

Fig. 3 shows these two sets of data plotted as logarithms against the reciprocal of absolute temperature. This method of plotting was used in order to obtain a linear relation, thus facilitating interpolation. The figure includes also a similar curve for values proportional to viscosity as obtained later by capillary flow.

We now have sufficient means for computing some sort of correction to be applied to each spindle to account for the additional torque exerted by virtue of its finite length. Since others have assumed that this may be expressed in terms of an additional length of spindle which remains constant for a constant radius, it will be so computed in this case. If l' is this additional length, we have

$$l' = l \left(\frac{\text{app. } \eta}{\text{true } \eta} - 1 \right).$$

Values for this correction computed from observed apparent viscosities and for those read from the curves in Fig. 2 have been included in Table I. For lengths greater than 5 cm a constant correction is obtained for each radius as follows:

$$R_1 = 0.5562 \text{ cm, } l' = 0.620 \text{ cm}$$

$$R_1 = 0.4769 \text{ cm, } l' = 0.517 \text{ cm}$$

from which we have the relation:

$$l' \text{ proportional to } (R_1)^{1.18},$$

indicating that the end correction when stated in terms of additional spindle length varies approximately as the first power of radius.

Temperature runs.

In order to determine more accurately the temperature viscosity relations for the oil, a run was made with each of four spindles, in each case leaving the spindle undisturbed while the temperature was varied. For this purpose two spindles, No. 101 and No. 107, from the previous runs were used, together with two others of special sizes.

Spindle No. 53. In a previous trial of various spindles with specially shaped ends it was found that one with conical ends showed the least variation of torque with variation of the distance from the bottom of the oil to the end of the spindle. Many subsequent determinations of glass viscosities

were made using such a spindle, consisting of platinum-iridium and having the following dimensions:

$$R_1 = 0.477 \text{ cm}, \quad l = 3.82 \text{ cm}, \quad V = 3.010 \text{ cc},$$

where l is the length of the cylindrical portion. Each end of the large portion of the spindle terminated in a 90° cone, while the whole was supported by a stem of about 0.16 cm diameter. A duplicate of this spindle was made of iron and called No. 53. Its distance of 1.5 cm from the upper and lower boundaries of the oil was measured to its cylindrical portion instead of to its pointed ends.

Spindle No. 152. Another spindle used considerably in glass is the one of "sillimanite" described in the previous paper on glass viscosities. It is nearly the same as spindle No. 101 but is held by a porcelain stem of $1/4$ " double-bore thermocouple tubing. A similar one was made of brass of dimensions:

$$R_1 = 0.5151 \text{ cm}, \quad l = 10.18 \text{ cm}, \quad R' = 0.3174 \text{ cm}, \quad V = 8.960 \text{ cc},$$

where R' is the radius of the stem. This was called spindle No. 152.

Fig. 3. Temperature runs in castor oil.

Table II gives the results for apparent viscosity of the castor oil obtained with these four spindles. The values for 20°C were interpolated on the curves in Fig. 3.

It is quite evident that the result obtained with spindle 152 at 19.47°C is in error since the slope of the curve for this spindle is less than for any of the others. Also, the similarity of No. 152 to No. 101 suggests an apparent viscosity at 20°C more nearly equal to 10.5. However, this trouble was not discovered until after the viscometer was dismantled and no redetermination was made.

Fig. 4. Apparent viscosities of glucose solution.

Measurements in glucose solution.

For the purpose of measuring relatively high viscosities, a supply of heavy glucose solution was obtained from a candy making concern. At the time it was drawn from the large supply tank this solution was placed in several pint jars and kept tightly sealed until used for the various runs. It was found in preliminary tests that evaporation could be completely stopped and surface film thereby avoided by covering the surface of the glucose with a thin layer of oil. Observation also showed that the oil had no tendency to creep between the glucose and its container, while a sharp surface always showed between the two liquids. Accordingly, as soon as the glucose had been placed in the cylindrical container of the viscometer and the spindle had been put in place, a small quantity of oil was added. As a further test of constant concentration of the solution, the first temperature used in each viscosity run was repeated at the end of the run. Good checks were consistently obtained.

TABLE III.

No. 101		No. 107		No. 53		No. 152	
Temp.	App. η	Temp.	App. η	Temp.	App. η	Temp.	App. η
19.45°C	3836	19.90	3707	19.70	3842	19.45	3650
23.64	1940	25.00	1627	25.24	1576	24.74	1581

35.15	385	34.30	436	34.20	447	34.60	411

Table III gives the observed apparent viscosities of the glucose as found by the four spindles used in the similar runs in castor oil. Fig. 4 shows these results plotted in terms of their logarithms against temperature. The line drawn through the points is for spindle No. 101. The other three spindles would give three curves parallel to and near this line.

TABLE IV

Spindle No.	Apparent η for glucose				Oil at 20°C.	η glucose \div η oil at 20°			
	20°	25°	30°	35°		20°	25°	30°	35°
101	3506	1574	760	392	10.50	334.0	150.0	72.4	37.3
107	3608	1630	777	396	10.99	328.2	148.3	70.7	36.0
53	3658	1637	789	410	11.04	331.0	148.1	71.4	37.7
152	3342	1521	744	385	10.10	331.0	150.7	73.6	38.1
					Mean	331.1	149.3	72.0	37.3
						$\pm 0.5\%$	$\pm 0.7\%$	$\pm 1.4\%$	$\pm 1.7\%$

Table IV gives values read from this family of curves corresponding to the various temperatures stated. From these values have been computed the viscosities of the glucose solution relative to castor oil at 20°C, as determined with the same spindles (Table II).

MEASUREMENT BY CAPILLARY FLOW METHOD

The second part of the investigation consisted of measuring the relative viscosities of castor oil and glucose solution over the same range of temperatures by capillary flow. The same capillary viscometer was used for both liquids and the rates of flow so regulated as to make the maximum rates of shear as nearly as possible the same as those which prevailed in the cylinder method.

Apparatus.

The thermostat used was essentially the same as that described above for the rotating cylinder apparatus, with the exception of one slight change. A side tube was sealed into the regulator just above the top of the mercury column, this tube terminating in a large bulb immersed in the water bath. The purpose of this was to reduce further the effect of changing room temperature on the pressure over the column.

Fig. 5 is a sketch of the viscometer. Two similar reservoirs r_1 and r_2 are connected by the capillary C selected for roundness and uniformity of bore. The dimensions of the bore were found to be:

$$R = 0.1175 \text{ cm}; R^4 = 1.905 \times 10^{-4} \text{ cm}^4; L = 9.992 \text{ cm}$$

The ends of the capillary were ground and polished perpendicular to the axis. DeKhotinsky cement was used for fastening into the reservoirs, care being taken to have the two sides as symmetrical as possible. To avoid slipping when the higher temperatures and pressures were used, the bottom part of the viscometer was buried in plaster of Paris as shown. The reservoirs are fitted with screw tops A made of brass. The tubes t_1 and t_2 lead to a system of stopcocks which allow either tube to be connected to pressure or suction systems or to the volumetric manometer at will. This manometer is constructed as shown at the right of Fig. 5. The left-hand leg a is graduated in cm and has been calibrated for volume. The liquid used is diphenyl oxide, chosen for its low viscosity and low vapor pressure. By keeping the levels equal in tubes a and b by means of the counter columns of mercury in c and d , the volume of flow through the capillary C can be followed and measured. This flow is corrected for temperature differences between the bath and the room by the following:

$$F = V(T_1/T_2)$$

where F is the actual flow through C , V the volume registered in the manometer, T_1 and T_2 the absolute temperatures of bath and room respectively.

The pressure system contains a large carboy for holding the pressures constant during measurements.

Measurements for castor oil.

Technique: For creating such a small rate of flow as was desired, very small pressures were necessary. This meant that a difference in level in the two reservoirs would have an effect on the rate of flow. The following method was used for avoiding error from this source: Both reservoirs were first opened to

Fig. 5. Sketch of viscometer.

atmospheric pressure and the liquid allowed to come to rest. One tube, e.g. t_1 , was then connected to the volumetric manometer, the columns a and b being first adjusted to about the 30 cm mark. A slight suction was then caused in r_2 and the oil made to flow back until the columns a and b reached the 10 cm mark or thereabouts. At this time r_2 was connected to the pressure

system and, keeping atmospheric pressure in r_1 by lowering d to keep a and b on a level, time readings were made for each 2 cm drop in a by means of a split-time watch. These time readings were then plotted against the corresponding column positions, giving a slightly curved line whose slope at 30 cm was the rate of flow corresponding to zero hydrostatic pressure.

In the case of castor oil, pressures were measured by means of a Nujol manometer and later converted to the usual cm of mercury units.

Results: The actual numerical results will not be quoted here. Fig. 6 shows them graphically, the two kinds of points plotted representing the two

Fig. 6. Pressure-flow relations for new castor oil.

directions of flow through the capillary. It is evident that the system is quite nearly symmetrical and that the relation between rate of flow and pressure is a linear one. The slopes are:

29.92°C	5.73
20.12	12.19
20.00 (extrapolated)	12.31

These slopes, proportional to viscosity, have been plotted in Fig. 3. The value obtained in this case for $\Delta \log \eta / \Delta (1/T)$ is 297 as compared with 297 for the concentric cylinders and 302 for values from the Smithsonian Tables. This indicates that the oil itself differs slightly from that for which the viscosities in the Tables are quoted.

Measurements for glucose solution.

Technique. In order to have about the same rates of flow in the glucose solution as in the oil, very much higher pressures were used. This fact made the effect of difference of level between the two reservoirs negligible in comparison with the other forces acting. It was, therefore, unnecessary to carry out the procedures as outlined above, the flows being now measured simply by taking the total time for a certain flow—usually 10 cm in the volumetric manometer.

Fig. 7. Pressure-flow relations for glucose solution.

A covering of oil over the glucose was used as before and bubbles were eliminated by warming and slightly reducing the pressure for a very short time. In this case mercury was used in the pressure manometer. No suction was used over the glucose at any time during the measurements. It was found necessary to use a soft wax in the stopcocks of the pressure system. Pressure was obtained from a cylinder of nitrogen by the use of a reducing valve, a stopcock being closed between the pressure system and the reducing valve during the flow observations.

Results. Fig. 7 shows the pressure-flow relations for the glucose solution. As in the case of castor oil, it is evident that the two directions of flow agree and that the relations are represented by straight lines. It may be said in this connection that any small difference observed in apparent viscosity as the pressures were decreased seemed to be toward lower values instead of toward high ones as would be expected if plasticity were present in the glucose.

The slopes of the observed pressure-flow lines are:

37.20°C	338 ± 4	24.75°C	1897 ± 21
30.12	847 ± 11	19.95	4256 ± 53

These values, proportional to viscosity, are plotted logarithmically in Fig. 4. Values for the reference temperatures, interpolated by means of this graph, are shown in Table V, together with viscosities relative to castor oil at 20°C, as obtained by the two methods.

TABLE V.

Temp.	Interpolated slope	Oil at 20°C	η relative to castor oil at 20°		Deviation of cylinders from capillary
			capillary	cylinders	
20°C	4220 ± 53	12.31	342.5 ± 1.3%	331.1 ± 0.5%	-3.4% (±1.8%)
25	1824 ± 21		148.1 ± 1.1%	149.3 ± 0.7%	+0.8% (±1.8%)
30	865 ± 11		70.3 ± 1.3%	72.0 ± 1.4%	+2.4% (±2.7%)
35	446 ± 6		36.2 ± 1.3%	37.3 ± 1.7%	+3.1% (±3.0%)

The table also gives the deviations of values of relative viscosity as obtained by the cylinders from those by capillary flow. The figure in parentheses following each of these deviations is the sum of the estimated probable errors for the two methods taken to represent the probable error to which the final comparison is subject. The fact that this deviation is zero for about 2000 poises, while it must be zero also for the viscosity of the oil, indicates that errors in the measurements themselves, and in the various graphical interpolations made, are responsible for all the deviations. If this can be considered true it may be said that the calibrating factor of the concentric cylinders remains constant over the range of viscosities between 5 and 3500 poises. In any case the deviation from constancy is very small.

Rates of shear.

In the rotating cylinder system, the expression for rate of shear is:

$$s = \frac{2\Omega R_1^2 R_2^2}{r^2(R_2^2 - R_1^2)}.$$

This reaches a maximum when r is its minimum value R_1 , or maximum rate of shear

$$S = \frac{2\Omega R_2^2}{R_2^2 - R_1^2} = 2.06\Omega \text{ approximately.}$$

The values of Ω used were from 0.233 to 0.524 radians/sec. The maximum rates of shear, then, ranged from

$$S = 0.48 \text{ to } 1.08 \text{ cm/sec/cm.}$$

In the capillary flow system, rate of shear is expressed by

$$s = \frac{-4rQ}{\pi R^4}$$

which reaches a maximum numerical value at $r = R$, or

$$S = \frac{-4Q}{\pi R^3}.$$

In the experiments reported above, Q was expressed in terms of cm of tube in the volumetric manometer. To convert the values to cc/sec. we must multiply the numbers by the volume of tube per cm (0.1131). This gives values of Q from 0.0045 to 0.017 for oil and from 0.0011 to 0.0113 for the glucose. Using $R^3 = 1.62 \times 10^{-3}$ we have $S = 3.54$ to 13.4 for oil and 0.86 to 8.9 for glucose. Although these limits do not correspond exactly to those found for the cylinders, they are of the same order of magnitude and actually overlap to some extent.

Capillary end correction.

The equation for viscosity by the capillary flow method is, since the kinetic energy correction is negligible,

$$\eta = \frac{\pi P R^4}{8Q} \left(\frac{1}{L + \lambda} \right)$$

where P is pressure in dynes/cm², Q volume rate of flow and R and L the radius and length respectively of the capillary. λ represents a length that must be added to L to give the effective length of the constriction through which the liquid must flow.

The viscosity of the castor oil at 20°C, found by the concentric cylinders is 9.99 poises. The slope P/Q found as 12.31 by capillary flow is in terms of cm of mercury per unit velocity of the column in the volumetric manometer. It is equivalent to 1.445×10^6 in c.g.s. units. Then we have

$$\begin{aligned} L + \lambda &= \frac{\pi \times 1.905 \times 10^{-4} \times 1.445 \times 10^6}{8 \times 9.99} \\ &= 10.83 \end{aligned}$$

But since $L = 9.99$ cm,

$$\lambda = 0.84 \text{ cm or about } 3.5 \text{ diameters.}$$

The experience of others has shown that λ is usually of the order of a few diameters.

Acknowledgment.

In conclusion, the writer wishes to express his appreciation for the assistance rendered by Dr. G. S. Fulcher in the preparation of this paper.

ERRATUM

THE DISPERSION FORMULA AND RAMAN EFFECT FOR THE SYMMETRICAL TOP

BY MORRIS MUSKAT

(Phys. Rev. **35**, 1262, 1930)

Exponents of the form $(2\pi i/h) t(W_a - W_b)$ should be preceded by a minus sign so that $\nu_{jk} = (W_j - W_k)/h$ and $\eta = +8\pi^2 A\nu/h$.

In the bracket of (21) read $[1 + \dots]$ and in (25) $(j \mp 2m)$.

In $R(\nu + \nu_{j, j+1})$ the parenthesis should be $(j^4 + 3j^3 + 2j^2 + j^2 m^2 + 8jm^2 + 12m^2)$ so that the numerical factor in $I(\nu + \nu_{j, j+1})$ becomes $128/3$.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Interpretation of the Visible Halogen Bands

The familiar absorption band spectra of the halogen molecules in the visible (and partly in the near ultraviolet) are commonly attributed to a ${}^1\Sigma \leftarrow {}^1\Sigma$ electron transition. That the lower level is ${}^1\Sigma$ is practically certain from the fact that Cl_2 is diamagnetic and from other considerations, while the ${}^1\Sigma$ character of the upper state is then indicated by the structure of the bands (one P and one R branch). Now it is known that both states dissociate into normal 2P halogen atoms (the lower probably into ${}^2P_{1/2} + {}^2P_{1/2}$, the upper certainly into ${}^2P_{1/2} + {}^2P_{3/2}$). According to the rules of Wigner and Witmer, it can be shown that two normal halogen atoms can give three ${}^1\Sigma$ states, namely two ${}^1\Sigma_g^+$ states and one ${}^1\Sigma_u^-$ state. The normal molecular state can in all probability be identified with one of the two ${}^1\Sigma_g^+$ states. Now a ${}^1\Sigma_g^+$ state can combine spectroscopically with another ${}^1\Sigma$ state only if the latter is of the ${}^1\Sigma_u^+$ type. Since no such state can be derived from normal atoms, and since the upper level of the halogen bands certainly is derived from normal atoms, it is evident that the bands cannot be of the ${}^1\Sigma \leftarrow {}^1\Sigma$ type. (The same conclusion would be reached if we assume ${}^1\Sigma_u^-$ for the normal state; this assumption is however almost certainly not appropriate.)

The upper state must then be a state of some kind other than ${}^1\Sigma$, fulfilling the following conditions: (1) it must be derivable from normal atoms; (2) it must be capable of combining spectroscopically with the ${}^1\Sigma^+$ normal state, giving a P and an R branch. The only

state which fulfils these conditions is a ${}^3\Pi_{0u}$ state. We must, however, assume that only half of the rotational levels of the ${}^3\Pi_0$ state are active (in an ordinary ${}^3\Pi_0$ state, there are two closely adjacent rotational levels for each value of J). This at first seemingly arbitrary assumption is made plausible by a consideration of the fact that the dissociation energy of the electron level in question is of the same order of magnitude as the energy of coupling between the L and S vectors in the halogen atom. Under these circumstances the two sets of rotational levels of ${}^3\Pi_0$ may behave as if belonging to two separate electron levels, which we shall call 0^+ and 0^- . The halogen band can be interpreted by assuming that only combinations with the 0^+ level are observed. As for the 0^- level, it may be that it has a very small dissociation energy so that it gives only a continuous band spectrum, or it may be that its combinations with the normal state (Q branches only, they should be) are weak.

A consequence of the above interpretation is that the excited state of the halogen bands should be paramagnetic. This is in harmony with certain magnetic phenomena observed with these bands.

Double Crystal Analysis of Scattered X-rays

A series of double crystal experiments has been completed to determine accurately the magnitude of the Compton shift. In order to do this, the angle of scattering was made

as near to 180° as possible, so that variations in the scattering angle would result in small variations of the wave-length change. A metal x-ray tube of small diameter and with two

aluminum windows 0.05 mm thick was used. In a typical run, this tube carried 70 m.a. at 50 K.V., though occasionally higher currents were used. The x-rays passed through one aluminum window and were incident upon a large block of graphite placed four mm from that window. X-rays scattered from the graphite passed back through this window, and emerged from the other window on the opposite side of the tube, after which they were limited by two lead slits before striking the first crystal. This means that the x-rays were scattered at nearly 180° . The direct beam of x-rays emerging from the second window was carefully shielded, so that the only x-rays reaching the first crystal were those scattered by the graphite or by the thin windows. A test showed that no x-rays were scattered by the windows themselves.

The x-rays, after having been limited by the slits were reflected by two calcite crystals, set at the proper angle. Those x-rays, which were reflected from the second crystal, entered a carefully shielded ionization chamber, filled with methyl bromide. The amount of ionization produced at various angles of the second crystal was measured by means of an electrometer system having 6000 mm/volt sensitivity and about 35 cm capacity. The two crystals used were polished and gave a rocking curve in the parallel position, which was 20 seconds wide at half maximum.

Five different spectra were taken to determine the position of the $\text{MoK}\alpha_1$ modified line. The $\text{K}\alpha_1$ and $\text{K}\alpha_2$ lines of the modified beam were clearly separated. Fluorescent rays from Mo were used to determine the position of the unmodified $\text{K}\alpha_1$ line. The value of $d\lambda$ obtained was 0.04721Å with a probable error of $\pm 0.00003\text{Å}$, on the basis of D (calcite) = 3.02904.

The effective angle of scattering was calculated from the geometry of the slit-window system by dividing the target face into segments of area, the scattering block into small volumes and evaluating the angle between each area and each volume. The extreme values of the scattering angle ϕ were 153° and 175° . The value of $1-\cos \phi$ determined in the above manner was 1.9479. It is estimated that this value is accurate to ± 0.003 . From the equation $d\lambda = (h/mc)(1-\cos \phi)$, one calculates for h/mc the value $0.02424 \pm 0.00004\text{Å}$. This may be compared with 0.02417Å, the value for h/mc when the mass of the electron is deduced from spectroscopic determinations, and with 0.02428Å, the value for h/mc when the mass of the electron is deduced from deflection methods.

A Remark on the Paper of R. C. Tolman: "Mechanical Treatment of Temperature Distribution in the Case of Radiation."

R. C. Tolman points out that heat, like every other form of energy, possesses weight, and that therefore gravitation must have an influence on the distribution of temperature throughout a system which has come to thermodynamic equilibrium. Tolman here observes: "The discovery of a dependence of equilibrium temperature on gravitational potential must be regarded as something essentially new in thermodynamics."¹

As against this I must remark that similar ideas have previously been expressed by my-

self.² In the publication referred to I gave some formulae, which differ from the corresponding ones given by Tolman only in some unessential details.

WILHELM ANDERSON

Tartu-Dorpat (Estonia).

¹ Richard C. Tolman, *Phys. Rev.* **35**, 904 (1930).

² Wilhelm Anderson, Über den Samazustand "ertser Art" und "zweiter Art," *Zeits. f. Physik* **58**, 440 (1929).

A Remark on the Foregoing Letter of W. Anderson

The Editor of the Physical Review has been good enough to send me a copy of the preceding letter before publication, and Dr. Anderson has also himself kindly sent me a reprint of the article to which he refers. In

this article Dr. Anderson has indeed expressed the opinion that the weight of energy should itself lead to a temperature gradient, and has thus given qualitative expression to an idea, which I believe to be essentially cor-

rect. Nevertheless, the quantitative implications of this idea can be ascertained with certainty only by a careful analysis in which the phenomena of gravitation are treated by the methods of general relativity. Such an analysis, however, is not presented by Dr. Anderson and I find myself unable to agree with the quantitative conclusions which he does obtain.

In considering the case of a system of gaseous molecules subjected to the action of gravity, Dr. Anderson does not make use of the idea that heat has weight, and comes to the conclusion that the temperature would fall to the absolute zero at levels too high for the molecules to obtain sufficient energy to reach. I should maintain on the other hand that in a treatment of thermodynamic equilibrium it was incorrect to consider the molecules separately from the radiation with which they are in equilibrium and that this radiation would have a finite temperature even at levels too high for the molecules to reach. Thus in the case of a spherical distribution of a perfect fluid, which could consist of molecules and radiation at lower levels and of pure radiation at higher levels, I should maintain that the temperature gradient would be given at all levels by my equation (54, loc. cit.)

$$\frac{d \log T_0}{dr} = -\frac{1}{2} \frac{d\nu}{dr} \quad (1)$$

and that there would be no discontinuity or drop to the absolute zero at levels too high for the molecules to reach.

In considering the case of pure radiation, Dr. Anderson does make use of the idea that energy has weight and proceeds in a manner in somewhat closer agreement with that which I should consider correct. Nevertheless, I believe that the non-relativistic treatment which he gives not only involves serious limitations but leads as well to a result which is essentially incorrect.

As to the limitations, it should be noted that this final result is expressed in terms of the quantities temperature T , height H , and gravitational acceleration g , which he does not interpret from the standpoint of the relativistic theory of gravitation. In place of his undefined quantity T he would presumably be willing to use the proper temperature T_0 which can be definitely defined as that measured by a local observer, but the

ideas of height H and gravitational acceleration g are necessarily restricted in their significance to fields weak enough so that the Newtonian treatment of gravitation becomes a correct approximation and this greatly limits the generality of his result.

Turning now to the correctness of the actual result which he does obtain for the temperature gradient in a field of radiation subjected to gravitational action, namely,

$$\frac{dT}{T} = -\frac{3}{4} \frac{g}{c^2} dH \quad (2)$$

we must compare this with the approximate result which can be obtained from my Eq. (1), when the gravitational field is weak enough so that the Newtonian treatment can be to some extent introduced as a first approximation. Under such circumstances we can then approximately identify the coordinate r with the height H and approximately replace the right hand side of the equation by $-g/c^2$, where g is the acceleration that would be experienced by a *slow moving* particle in the field in question. We thus obtain the different result

$$\frac{dT_0}{T_0} = -\frac{g}{c^2} dH \quad (3)$$

The incorrect factor $3/4$ appearing in Dr. Anderson's Eq. (2) is connected of course with the well-known fact, verified by the bending of light in the gravitational field of the sun, that the Newtonian approximations do not lead to correct results even in weak fields when particles are considered which are moving with velocities in the neighborhood of that of light.

At first sight it might appear as if the difference between the two formulae was an unessential detail, as suggested by Dr. Anderson. With this, however, I cannot agree since as shown in my article the formula (3) applies to matter in a weak gravitational field, and it would certainly be a thermodynamic catastrophe if a different formula (2) had to be applied to radiation, since this would force us to the conclusion that matter and the radiation in contact with it at a given level had to have *different* proper temperatures in order to be in equilibrium.

In conclusion, I am very grateful to Dr. Anderson for informing me of his earlier expression of the idea that the weight of energy should lead to a temperature gradient. Since I do not agree, however, with the con-

clusions as to temperature gradient drawn by Dr. Anderson and do not know of any other general and coherent treatment of the thermodynamic consequences of this idea, I hope Dr. Anderson will understand why

I still feel inclined to maintain that the discovery of the *correct* dependence of equilibrium temperature on gravitational potential must be regarded as something essentially new in thermodynamics.

Raman Spectra of Geometric Isomers

An investigation of the Raman spectra of the geometric isomers, ethyl fumarate and ethyl maleate, has disclosed a difference between them. In the spectrum of ethyl maleate we find a broad diffuse band at 4693A to 4699A. In the case of ethyl fumarate, the band is replaced by two distinct lines at 4692A and 4698A. The frequency difference between modified and unmodified lines for the first case is from 1636 cm^{-1} to 1683 cm^{-1} and for the second case, 1633 cm^{-1} and 1661 cm^{-1} . It has been suggested by others that a shift of about 1600 wave numbers is associated with the vibration frequency along a carbon oxygen double bond. In the accepted structural formulae of the two esters,

the only C=O double bonds are exterior to the chain. In the case of the maleate, the C=O double bonds are not symmetrically arranged with regard to either the double bond connecting the two chains, or the center of mass of the molecule. In the fumarate the C=O double bonds are symmetrically arranged with regard to this bond, which is also the center of mass of the system. In the spectrum of the maleate, the vibration along the two C=O double bonds may give rise to the broad band, while in the fumarate, they apparently give the separate lines.

The average value of the frequency shifts for the other lines common to both substances are,

$$\Delta\nu = 865, 1169, 1212, 1732, 3033, 3061\text{ cm}^{-1}.$$

The fumarate has in addition two very faint lines corresponding to a shift of 888 and 1361 cm^{-1} .

A Method Offered as a Means of Computing Planck's Constant without Involving the Charge on the Electron

One notes that, numerically, the magnetic moment of an electron in ergs per gauss is equal to its charge in coulombs:

$$\begin{aligned} 3\frac{1}{2}he/4\pi mc &= e/c = 1.59 \cdot 10^{-20}; \text{ whence} \\ 3\frac{1}{2}h/4\pi &= m \quad \text{or} \\ h &= 4\pi/3\frac{1}{2}. \end{aligned}$$

Inserting the spectroscopic value of m , $0.9035 \cdot 10^{-27}$, one finds that $h = 6.555 \cdot 10^{-27}$ erg sec. To make the units cancel properly, one must give the spin vector the dimensions of seconds per centimeter squared, or time per unit area, dimensions which do not seem to have any obvious physical meaning. However, it passes the bounds of plausibility that the magnetic moment should be found numerically equal to the charge, or the angular momentum to the mass, without any physical basis. Two such coincidences to several significant figures in a range so enormous

would have a vanishingly small possibility of occurring, were there no physical basis for such concordance.

Unfortunately, the units are different even in ultimate rational units, for in this system charge, being a world-invariant, is expressed as a pure number; whereas magnetic moment is not.

One is reminded of the theory that mass is merely the effect of self-inductance or electrical inertia. Thus the mass of the electron might be due to the self-inductance of the current representing the spin, if a spinning electron may be said to constitute a current. Thus the equating of the angular momentum of the electron to its mass is qualitatively reasonable and could doubtless be made quantitatively exact by the use of an appropriate model.

It is to be noticed that $6.555 \cdot 10^{-27}$ erg

sec. as a value of h falls just within the limit of error which Birge allows. If M_h/m_e is taken as 1840 the agreement is better, h equalling $6.552 \cdot 10^{-27}$ erg sec.

As stated, the advantage of this method of calculating h is that it does not involve the charge on the electron, since the value of the mass of the electron may be found without reference to its charge as Houston has done by the relation between the Rydberg constants for hydrogen and ionized helium. Thus we may use this value of h for computing e . According to Birge's article in the first issue of the Physical Review Supplement, by the theory of ultimate rational units, the reciprocal of the fine structure constant equals 137.3, whence, using $6.555 \cdot 10^{-27}$ as the value of h , e is found to be $4.773 \cdot 10^{-10}$ e.s.u. The uncertainty in this value lies entirely in h , and therefore in the experimental value of the mass of the electron. This is about one-

twentieth of one percent, and since h occurs under a radical when one solves for e in the fine structure constant equation, the uncertainty in e is only $0.002 \cdot 10^{-10}$.

If the deflection mass instead of the spectroscopic mass of the electron is used, very disparate results are obtained for h and e .

The value of Avogadro's number obtained with the above value of e is identical with Birge's value of N .

It remains then to find some reason for the numerical equivalence of the magnetic moment and the charge of the electron, or of its angular momentum and mass, and the values of some of the more important physical constants may be established with less uncertainty than heretofore.

Gas Discharge Wave-Length List in Extreme Ultraviolet

We have prepared a list, arranged in order of wave-length, of the published lines in the extreme ultraviolet ($\lambda 2500$ to $\lambda 100$) arising from discharges in gases. The elements included are hydrogen, helium, carbon, nitrogen, oxygen, neon, sodium, silicon, argon, and mercury. Thanks to support from the Carnegie Institution of Washington, it has been possible to publish a limited mimeographed edition of the list, copies of which have been sent

to a few spectroscopists to whom we thought it might be of particular use. We should be glad to give copies to any others who may write requesting them.

BOOK REVIEWS

Einführung in die Wellenmechanik. L. DE BROGLIE. translated (from French to German) by R. Peierls. 219 pages. Akademische Verlagsgesellschaft, Leipzig, 1929. Price RM 13.80 bound.

The discoverer of the wave nature of the electron has written here a clear account of the development of wave mechanics starting with an account of classical mechanics and building on the analogy between the principle of least action and Fermat's principle in geometrical optics. The bulk of the book is occupied with a careful discussion of free motion of a particle and its relation to the wave packets from the standpoint of the uncertainty principle of Heisenberg and Bohr. In the last chapters elementary cases of quantization of energy levels in cases of periodic motion are discussed. There is no treatment of the radiation process nor of equivalence degeneracy in problems involving several equivalent particles nor of electron spin.

E. U. CONDON

Dielectric Phenomena in High Voltage Engineering. F. W. PEEK, JR. Pp. 410, figs. 267. McGraw-Hill Book Co., New York, 1929. Price \$5.00.

This is a third edition, the first having appeared in 1915. While the arrangement shows the effect of growth, involving some repetition, yet it has been thoroughly revised and brought up to date and constitutes an authoritative and exhaustive as well as very readable treatment of corona and spark-over phenomena. Mr. Peek is a leader in the field of high voltage engineering, and a large part of the material in the book is taken from his own experiments and those of his associates in the General Electric Company. Corona and spark-over in air, including lightning, are treated with great thoroughness, those in liquids and solids more briefly. The new material added to this third edition includes the results of recent studies of corona, extensive studies of the impulse breakdown of gases and insulation, cathode-ray studies of impulse breakdown in power transformers and other apparatus, and spark-over phenomena at very high voltages. Studies of artificial lightning with the author's five million volt impulse generator are of special interest.

The book contains mainly experimental data, with empirical laws and formulae, and relatively little mathematics.

ALBERT W. HULL

Elements of Electricity. ANTHONY ZELENY. Pp. xxiii+438, 267 figures, 12 appendices, McGraw-Hill Book Co., New York, 1930, Price \$3.00.

This excellent elementary text is the outgrowth of many years of teaching the subject of electricity to engineering, premedical and arts students in a first course of college physics. The subject is developed in a large number (30) of short chapters, at the end of each of which are a number of questions, problems and suggested experiments for lecture demonstration. The book is profusely illustrated by line drawings and half tones, including pictures of many of the pioneers in the subject. The appendices contain tables of numerical constants, definitions of electric and magnetic units, collections of laws, important dates, answers to problems, tables of squares, cubes and reciprocals, trigonometrical functions, and logarithms.

The text being designed for a first course, the subject is developed with the minimum of mathematical detail, no analysis more advanced than elementary algebra and trigonometry being used. The electron theory is introduced in the second article, and the subject is treated from this point of view throughout. After a brief discussion of electric charges and electric forces in the first chapter, the subject of magnetostatics is taken up, after which electrostatics is treated in more detail. The characteristics of the transformer and the subject of the generation and transmission of electric power are dealt with more extensively than in the usual elementary text, and chapters are devoted to discharge in gases at low pressure; measurement of

velocity, charge, and mass of electrons, protons and isotopes; production and detection of electromagnetic waves; electrical communication; and atmospheric electricity.

The outstanding feature of the book is the adoption by the author of modern points of view which have been all too slow in finding their way into elementary texts. Consequently the student does not have to "unlearn" much of what he reads before being able to advance further in the subject. This attitude is well exemplified by the author's sensible treatment of the ether. While not discarding the term itself, he points out the difficulties which have led to the abandonment of the old elastic solid medium, and makes clear that the subject can be treated without any reference to the ether, a form of treatment which he employs throughout. Again he emphasizes the importance of the elementary electric and magnetic fields associated with each electron and proton, as against the concept of the resultant field. Altogether too few writers seem to recognize the fact that "except in electrostatics and magnetostatics) it is these elementary fields which are fundamental and not the resultant field. Lack of recognition of this important fact can all too easily lead to grievous errors.

In his treatment of currents in metallic circuits the author takes the direction of flow of electrons as fundamental instead of that of the current. Whether this is pedagogically advantageous or not seems somewhat questionable to the reviewer, since it is likely to cause confusion in determining the direction of the magnetic field due to the current. In dealing with induced electromotive forces the author explains how the field of an accelerated electron urges neighboring free electrons in the opposite direction. This gives the student a picture of the mechanism of induction far superior to the usual treatment.

While certain minor details may be criticized, the book as a whole appeals very strongly to the reviewer as one which will give the elementary student an excellent foundation in the subject of electromagnetism. It is well printed, the type being of sufficient size to facilitate reading.

LEIGH PAGE

The Size of the Universe. LUDWIG SILBERSTEIN. Pp. viii+215, figs. 11. Oxford University Press, London 1930. \$3.50.

In this book Dr. Silberstein reexpresses and extends his previous treatment of the determination of the curvature radius of spacetime. The treatment presupposes the de Sitter line element for the universe in a static form, and makes no assumption as to a greater inherent probability of receding rather than approaching objects, in contradistinction to the treatment of Weyl and the corresponding non-static form for the de Sitter line element of Robertson. The estimates of radius are then based on correlations between the radial velocity and distance obtained from the consideration of five different groups of celestial objects. The groups used together with the varying values obtained for the radius were as follows:

- a. Eighteen globular clusters and the two Magellanic Clouds, 3.61×10^7 parsecs.
- b. Thirty-eight spiral nebulae, 7.32×10^8 parsecs.
- c. Twenty-nine cepheid variables, 1.46×10^6 parsecs.
- d. Thirty-five O-stars, 1.58×10^6 parsecs.
- e. Four hundred and fifty-nine stars from Young and Harper's list, 1.96×10^6 parsecs.

The most recent Mount Wilson results, of Hubble and Humason, showing a linear relation between apparent velocity of recession and distance of the extragalactic nebulae out to the enormous range of approximately 2.5×10^7 parsecs, were not available to Dr. Silberstein at the time of writing. In view of these facts, however, it would now appear to the present reviewer that cosmologies such as Silberstein's which do not expressly take account of the exclusively recessional motion of all the most distant objects would have to be superseded. In addition, it would seem that the use of stars within our own galactic system would have to be abandoned in favor of extragalactic objects for any form of cosmological determination.

Dr. Silberstein expresses throughout the book a most violent and unnecessary antipathy to the Einstein line element for the universe. This antipathy leads him to devote a whole chapter to a satiric and unjustified attack on the work of Hubble, for the sole apparent reason that Hubble has once made an estimate of the average density of matter in the universe which

could then be inserted in Einstein's formula for the radius of the universe. As a matter of fact, the work of Hubble and his collaborator Humason is by far the most important of all the observational contributions to the problems of cosmogony that have been made, and the estimate of mean density which he obtained is of great interest in interpreting the new non-static line element which now appears to be more satisfactory for cosmological speculations than either that of de Sitter or of Einstein.

The book exhibits a wealth of mathematical erudition and is written in a pungent and often illuminating style, although sometimes the style becomes perhaps too extravagant as for example in the following passage:

"If $a=r^*$, we have $\theta = \infty$, and, as we see directly from (108), each star will move uniformly on a straight line, utterly asocial, as it were, that, is, disregarding the presence of all other members of this galactic community. Thus, if their instantaneous velocities are haphazard in size and direction, the crowd will sooner or later be scattered to the four winds as in spite of all visual appearances; there is nothing to hold them together. And the more so, if the galaxy has swollen up beyond that critical radius of its mass total, the orbits then degenerating, by (109), into hyperbolic branches. Is in the wording of these results an illusion implied to communities of humans, a score or so of Nation-Galaxies, now stiffly coherent, now torn asunder, not only by foreign interference but as often by internal strife, with the greed and lust of power of the 'upper thousand' to urge the territorial expansion (growing a), and a huge majority of what some modern sociologists† refer to as the 'international mob,' but too eager to profit by every tumult, to tear down all social bonds, to set out on world-wide vagabondage, and mingling with deserters of other galaxies, sweep down every civilization, like the sand-laden winds of Sahara obliterate every hillock or oasis casually formed of stray particles through long years of slow and patient toil? I prefer to leave this question to my readers, the more so as I am the last man to desire to undermine their possibly strong confidence in a steady evolution and betterment of assemblages, both human and celestial, in an ever-mounting 'progress,' that is, as opposed to the hurricane-like 'cycloism' which is (not without weighty reasons) advocated by the aforesaid group of social philosophers. At any rate, some time spent now and then on such comparisons will not be entirely lost, provided that these are tempered by caution and self-criticism, and not poisoned by passion."

RICHARD C. TOLMAN

Grundzüge der theoretischen und angewandten Elektrochemie. GEORG GRUBE. Pp. xii+495, figs. 165. Published by Theodor Steinkopff, Dresden und Leipzig, 1930. Price bound, RM 30.

This treatise will be of treat interest to chemists and can be highly recommended to their attention. The author gives a clear and adequate account of theoretical electrochemistry in the first four chapters while he devotes the eight remaining chapters to numerous technical applications. The style is clear and the point of view is strictly up-to-date. It is a very satisfactory book.

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

MINUTES OF THE ITHACA MEETING, JUNE 19-21, 1930

The 165th meeting of the American Physical Society was held in Ithaca, New York on Thursday, Friday and Saturday, June 19, 20 and 21.

The Council authorized a \$1.00 registration fee to be collected from the members attending this meeting.

The scientific sessions were all held in Rockefeller Hall. The presiding officers were Herbert E. Ives, John T. Tate, Dayton C. Miller, Ernest Merritt and Karl T. Compton.

On Wednesday, June 18, the Society was invited to be the guest of The Corning Glass Works for luncheon and an inspection trip through the Glass Works. There were 220 present at the luncheon at which we were honored by the presence of the Honorable A. B. Houghton.

On Thursday morning, June 19, from 10 a.m. to 1 p.m. the regular program for the reading of the thirty-three contributed papers was held. On Thursday afternoon a picnic was held at Buttermilk Falls and was attended by 247 persons.

On Friday morning, June 20, at 10 o'clock there were two invited papers on Astrophysics: S. A. Mitchell, Director, McCormick Observatory, University of Virginia, "Atomic Structure under Conditions of Temperature and Pressure Found at the Sun's Surface" and J. Q. Stewart, Princeton University Observatory, "The General Problems of Astrophysics with Special Reference to the Opacity of Gases." On Friday afternoon at 2 o'clock Sir William Bragg delivered an address on "Faraday's Diary." The attendance at this meeting was over 500. Among those attending this lecture were the delegates to the convention of Colloidal Chemists being held in Ithaca at the same time.

On Saturday morning, June 21, there were invited papers by F. Zwicky on "Secondary Structure of Crystals" and Arthur H. Compton on "X-ray Scattering and Atomic Structure."

In the afternoons of Thursday, Friday and Saturday informal conferences were held on the following topics: wave mechanics, dielectrics, biophysics, ionic and electronic emission, luminescence, astrophysics, electrons in metals, physical constants, molecular spectra, nuclei, quantum theory, x-rays and radio waves.

The delegates and their friends were housed in Risely Hall, one of the dormitories of the University. They all dined together in the beautiful dining room of this hall thus affording a most satisfactory opportunity to those attending the meeting to get together socially.

Meeting of the Council: At its meeting held on Friday morning, June 20, one person was elected to fellowship, one was transferred from membership to fellowship and nineteen were elected to membership. *Elected to Fellowship:* William Albert Noyes Jr. *Transferred from Membership to Fellowship:* J. J. Weigle. *Elected to Membership:* Warren F. Anderson, W. E. Bahls, Earle M. Bigsbee, Harry F. Blake, Charles P. Boner, Henry A. Boorse, Malcolm G. Colby, Ching Hsien Li, David Mann, F. L. Mears, Emerson M. Pugh, Leo J. Rysko, George H. Shortley Jr., Charles W. Sidney, Lewis K. Sillcox, Roger S. Strout, John H. Teeple, J. E. White, and Allan Williams.

The following resolution was passed by the Council and acclaimed by unanimous vote at the regular session of the Society on Saturday morning:

"That on behalf of the Council and of the membership of the American Physical Society we express to the local committee on arrangements, and to all those who assisted them, our great appreciation of the cordial hospitality and the splendid provisions they have made to make this first summer meeting of the Society so enjoyable and successful. We recall with pleasure that the Physical Review as well as the Society of Sigma Xi had their birth on this campus and we begin to appreciate this genius for giving new movements a vital beginning."

The regular program of the American Physical Society consisted of 33 papers. Numbers 15, 25, 28, 32, and 33 were read by title. The abstracts of these papers are given in the following pages. An **Author Index** will be found at the end.

W. L. SEVERINGHAUS, *Secretary*

ABSTRACTS

1. A new type of glow-discharge tube. HERBERT J. REICH, *University of Illinois*.—Several types of glow-discharge tubes are somewhat limited in their field of usefulness by the fact that the extinction potential is considerably lower than the ignition potential, making it difficult to control or stop the current after discharge commences. This difficulty may be overcome by incorporating an electron gun in the tube, and shooting a stream of electrons at high velocity between or through the glow electrodes. The discharge may thus be completely controlled at all times by a very small variation in the potential of the control electrode of the electron gun. A study of the characteristic curves of such a tube reveals a number of very interesting operating characteristics.

2. Preliminary measurements of the mean free path of potassium atoms in nitrogen. J. J. WEIGLE AND M. S. PLESSET, *University of Pittsburgh*.—The method of Taylor (*Zeits. f. Physik* 57, 242 (1929)) for the detection of beams of potassium atoms was used for a direct determination of their mean free path. A steel furnace with a single slit contained the potassium and was heated to about 150°C. At a distance of 10 cm a tungsten filament parallel to the slit, and surrounded by a slotted brass cylinder was used as a detector. The potassium atoms impinging on the hot filament are ionized and drawn to the cylinder by a suitable difference of potential. This positive ion current was measured as a function of the pressure of nitrogen filling the space between the filament and slit. Nitrogen pressures ranged from 10^{-2} to 10^{-6} cm of mercury. These ion currents are given by the equation $I = I_0 e^{-x/\lambda(p)}$ where I_0 is a constant, $\lambda(p)$ the mean free path at a given pressure p , and x the distance between the slit and filament. As λ is a known function of the average of the diameters of the potassium atom and nitrogen

molecule, this average was obtained from our measurements which gave values between 3×10^{-9} and 5×10^{-9} cm. These results are unexpectedly small. Experiments with a different apparatus are contemplated to disprove or confirm these preliminary results.

3. Organic reactions in gaseous electrical discharge. ERNEST G. LINDER, *Cornell University*.—A study of electrical discharge in a series of straight chain paraffin hydrocarbons indicates that the phenomenon is similar to that of electrolytic conduction in liquids, in so far as the amount of reaction (i.e., the amount of hydrogen liberated) appears to be proportional to the current, and independent of vapor pressure and voltage. There seems to be a simple relation between molecular size and the amount of hydrogen liberated.

4. On the recombination of electrons with caesium ions. E. H. KURTH, *California Institute of Technology*. (Introduced by F. Zwicky).—An apparatus was constructed in which electrons emitted from a caesium-on-tungsten oxide surface could be accelerated into an equipotential inclosure. A beam of caesium ions generated by a tungsten filament source and projected through the electron atmosphere in the box was collected on a plate. Electron currents up to 200 microamperes could be obtained with a few volts potential difference to the box. Positive currents were measured down to 10^{-9} amperes. When the electron velocities were varied over the range in which captures by caesium ions might be expected from the work of Davis and Barnes, no measurable decrease in the positive beam current was ever observed. The apparatus is being modified to permit tests for a considerably greater ratio of electron to positive currents.

5. Potential drop-current relations of a Geissler discharge from a hollow cathode. C. H. THOMAS, *Westinghouse Lamp Co., Bloomfield, N. J.*.—When a cold electrode, drilled to a depth $1/2$ inch with a drill 0.076 inch in diameter was used as a cathode in neon gas at pressures between 5 and 70 mm with electrode separation of 15 mm the cathode glow concentrated almost entirely in the hole. Under these conditions the potential drop-current curve for a thorium cathode shows a maximum in potential drop at a current of about 25 milliamperes. This potential drop decreases to a minimum at 50 milliamperes and subsequently attains a second maximum at 80–90 milliamperes. At a higher current a further decrease in potential drop resulted from thermionic emission. Similar curves for iron, misch meal and throrium-barium oxide cathodes in neon show a maximum at about 25 milliamperes but beyond that current their similarity to thorium curves disappears. Similar effects were observed in helium and argon. Potential drop-pressure curves for a cathode drilled with a 0.076 inch hole are given as well as the potential drop-size of hole curves which show that there is a minimum pressure for a given size hole in order that the cathode glow will concentrate in the hole. A hollow iron cathode in hydrogen at 23 mm pressure caused a decrease in the potential drop from 440 volts to 405 volts as the current was increased from 30 to 50 milliamperes.

6. The electrodeless discharge in mercury vapor. HERSCHEL SMITH, W. A. LYNCH AND NORMAN HILBERRY, *New York University, University Heights*.—The electrodeless discharge produced in Hg vapor inside the solenoid of a high frequency C. W. oscillator is studied in the pressure range between 0.004 mm and 0.8 mm of Hg. The characteristics of the two types of discharges reported by various authors (MacKinnon, Phil. Mag. Nov. 1929, Brasefield, Phys. Rev. May, 1930) are investigated in detail. Direct experimental evidence is given as to the electrostatic nature of the "glow" discharge and to the electromagnetic nature of the "arc" type discharge. Electromagnetic forces in themselves are found to be insufficient for the formation of the discharge but are sufficient for its maintenance. The "arc" type discharge is shown to be the more familiar ring discharge excited by damped oscillations. The currents in the oscillator coil necessary for the excitation of both types of discharge are examined as a function of the pressure at various frequencies. The curve for the glow discharge has a minimum within the given pressure range while that of the "arc" type discharge has both a minimum and a maximum. The form of these curves would seem to indicate the necessity for a complete revision of the present theories.

7. **Effect of collisions on potential distribution in positive ion sheaths.** H. P. ROBERTSON AND P. M. MORSE, *Princeton University*.—The potential distribution in a plane positive ion sheath is derived under the assumptions (1) an ion gives up a fraction θ of its kinetic energy at each collision, (2) the ions may be considered as following the lines of force and (3) the density of charge may be taken as i/v where v is the root mean square of the actual ionic velocities. The justification of assumption (2) is based on the considerations of v. Hippel, and that of (3) on the approximate agreement of dependence of potential on initial velocity for zero pressure with that obtained by previous workers (Schottky, Epstein, Fry, Langmuir). The rigorous solution of this problem gives the field strength and mean forward kinetic energy of the ions at any point in the sheath. The corresponding problem for cylindrical or spherical cathodes cannot be rigorously solved by the same methods, but can be treated by a method of approximations based on the rigorous solution for the plane case.

8. **The Hall effect in tellurium amalgams.** P. I. WOLD AND J. M. HYATT, *Union College*.—Certain aspects of the study of the Hall effect in crystalline materials suggested an attempt to make Te-Hg alloys. Amalgams were obtained of about 30% tellurium which were plastic when fresh but which became, in a few hours, quite hard and very friable. The plastic amalgam was placed in a mold as quickly as feasible and measurements on the Hall effect, the specific resistance and the longitudinal effect were started. The Hall effect commenced with very small values and built up steadily for two or three days. The Hall constants, after such time, were as high as 0.9, which is from 100 to 500 times the value when the amalgam was a half hour old. The authors are not aware of any previous case in which Hall effect has grown with time when temperature was constant and as a new phenomenon it seems to be of special interest. X-ray crystal photographs were taken of a sample of the amalgam as soon after making as possible and photographs taken within an hour show crystalline structure apparently as strongly as when two days old. The longitudinal effect started with very low values and increased steadily in about the same way as the Hall effect.

9. **Contact resistance and microphonic action.** FRANK GRAY, *Bell Telephone Laboratories, Inc.*—A mathematical theory is developed to explain the fact that conductivity of a contact between two carbon spheres changes with the force pressing the spheres together. It is assumed that the surface roughness of the carbon is equivalent to an assembly of minute spherical hills. On account of the elasticity of the material, both the macroscopic area of contact between the spheres and the microscopic areas of contact between the hills increase with contact force. The resulting relation between the contact resistance R and the contact force F is $R = A/F^{1/3} + B/F^{7/9}$ where A and B are constants. The last term of this equation, contributed by surface roughness, is almost the same as the corresponding term of the equation, $R = A/F^{1/3} + B/F^{6/9}$ which was developed by Professor P. O. Pedersen [Electrician, Feb. 4, 1916] on the assumption that carbon is covered with a thin, high resistance film. In other words, surface roughness behaves almost identically with a non-variable, high resistance film. Higher degrees of roughness increase the exponent of the last term. In the limit it becomes unity, and the roughness resistance then varies inversely as the contact force.

10. **Contact resistance and microphonic action.** F. S. GOUCHER, *Bell Telephone Laboratories, Inc.*—Previous work has shown that the conducting portions of contacts between single granules of microphone carbon are of the nature of carbon and that variations in contact area occur when the contact resistance is varied in a reversible resistance force cycle. An experimental study of the slopes of these reversible characteristics both for single contacts and aggregates shows them to be of the form $R = \text{const}(F)^{-n}$. The exponent n varies from cycle to cycle for equal force limits and the average value depends on the force limits. A maximum mean value independent of the force limits over a wide range, is obtained with the aggregates. This value is in agreement with the exponent in the second term of Gray's equation $R = (A/F^{1/3}) + (B/F^{7/9})$ [previous abstract] which indicates that an aggregate of contacts may, under certain conditions, behave as though it were a single contact between spheres having a rough surface. Values of n less than $1/3$ are obtained with both single contacts and aggregates. This is attributed to the effect of cohesive forces the existence of which was demonstrated by the sticking of contacts.

11. **Work functions and thermionic and constant "A" determined for thoriated tungsten.** W. B. NOTTINGHAM, *Bartol Research Foundation*.—The work function of a type T thoriated tungsten filament was determined with a 3.5 volt accelerating potential by measuring the thermionic current as a function of temperature over the range 1045°K to 1340°K. With the filament activated to give the maximum emission at 1100°K with a 20 volt accelerating potential, the effective work function ϕ' with 3.5 volts was found to be 2.59 volts. From measurements of the current-potential relationship at 1100°K, it was found that the 3.5 volt accelerating potential had reduced the work function by $\Delta\phi = 0.56$ volt. The work function at zero field is $\phi' + \Delta\phi = \phi_0 = 3.15$ volts. Using this value of ϕ_0 and the measured current, the thermionic constant is $A = 59.0$. Measurements made with a thorium covering *thicker* than that required to give the maximum emission as above, gave $\phi' = 2.8$ volts with 3.5 volts accelerating potential, $\Delta\phi = 0.3$ volt and therefore $\phi_0 = 3.1$ volts and $A = 56.0$. These data indicate that abnormally low values of A previously reported can be accounted for by the fact that the work functions were not measured at zero field. Langmuir found the contact potential between thoriated tungsten and clean tungsten to be 1.46 volts. Accordingly the work function of thoriated tungsten should be 4.53—1.46 = 3.07 volts which agrees with the above.

12. **The relation between the number of electrons ejected photoelectrically from the cathode and the time lag of the spark.** JOHN A. TIEDEMAN, *University of Virginia*. If the ions usually present in a spark gap in ordinary air are carefully removed by sweeping potentials an impulsive field of 75,000 volts/cm can be applied for at least 10^{-6} sec. without electrical breakdown. Strong ultraviolet irradiation of the cathode reduces the time lag to less than 10^{-8} sec. By means of biasing potentials and a steady source of ultraviolet light electrons could be liberated from the cathode only during the existence of a high electric field. The time lags were measured by the Lichtenberg figure method (Pedersen, *Ann. d. Physik* 71, 317 (1923)). By controlling the intensity of ultraviolet light on the cathode and the magnitude of the applied surge potential the time required for a known number of electrons to start the discharge in a field of known strength could be obtained. Between a Zn cathode and a steel anode spaced 2 mm electrons were ejected from the cathode at the rate of one in 3.3×10^{-9} sec. in an impulsive field with a maximum value of 75,000 volts/cm applied by a second spark, producing a time lag of 1.5×10^{-8} sec. while under the same conditions one electron per 9.5×10^{-9} sec. gave a time lag of 2.2×10^{-8} sec.

13. **Inhibition of photoelectric emission by near infrared light.** A. R. OLPIN, *Bell Telephone Laboratories, Inc.*—The response to potassium photoelectric cells to white light is greatly increased when small amounts of bromine or iodine vapor are distilled onto the cathode surface. Spectral distribution curves for cells so treated show a general increase in the response to light of all wave-lengths and a more marked increase to light at both ends of the visible spectrum. There is no measurable electron emission when the cells are irradiated with infrared light obtained by passing white light of color temperature 2848°K. through a #87 EK Wratten filter. If, however, the cathode already is emitting electrons under excitation with visible light when irradiation with infrared light occurs, a marked *decrease* in the photoelectric current is noted. Investigation shows that this decrease occurs only in the spectral regions where abnormally large increases are observed without the infrared light, and may amount to well over fifty percent for certain wave-lengths. Data showing some of the properties of this new effect, which has been observed for both potassium and sodium cells, are included. The phenomenon is closely analogous to the extinction of phosphorescence and destruction of the latent image on photographic plates by infrared radiations.

14. **On chain reactions caused by physical structure.** N. RASHEVSKY, *Westinghouse E. and M. Co., East Pittsburgh*.—In a previous paper (*Zeits. f. Physik* 59, 558 (1930)) it has been shown that when a substance is formed as a result of a reaction in a solution and is itself soluble in the surrounding liquid, this substance may exist as a separate phase, in shape of small drops, provided the size of the drops is above a certain critical value. Such drops cannot be formed spontaneously, but will continue to grow if brought from outside into the liquid. In the present paper, the case is considered, that the drop is constituted of several substances. Due to the interaction of the phenomena of diffusion and dissolution, the formation of the different sub-

stances will follow a definite order. Below a certain size, the drop cannot exist at all. Above it, it can be constituted only by one substance. With increasing size, the number of substances constituting the drop, increases. Applications to biological phenomena are discussed.

15. The corresponding state of maximum surface tension of saturated vapors. J. L. SHERESHEFSKY, *Mellon Institute of Industrial Research*. (Introduced by Paul D. Foote.)—The surface tension of a liquid is given by the expression (1) $\sigma = (rh/2)(\rho_1 - \rho_2)$, where h is the height of rise in a capillary of radius r , and ρ_1 and ρ_2 the densities of the liquid and vapor respectively. Writing the equation in the form $\sigma_r = rhe_1/2 - rhe_2/2$ and applying Antonow's rule, $rhe_1/2$ may be conceived as the true surface tension of the liquid, σ_r the relative surface tension, and (2) $\sigma_r = rhe_2/2$ where $rhe_2/2$ is defined as the surface tension of the vapor. Combining (1), (2), McLeods equation [$\sigma_r = c(\rho_1 - \rho_2)^{1/4}$] and Goldhammer's equation [$\rho_1 - \rho_2 = a(1 - T/T_c)^{1/3}$], an expression is obtained relating the surface tension of the vapor with the temperature, (3) $\sigma_v = K(1 - T/T_c)\rho_2$. It was found that σ_v goes through a maximum in the neighborhood of the critical temperature. Differentiating (3) the position of the maximum point is given by

$$(4) \quad \frac{d \log \rho_2}{dT} = \frac{0.4343}{T_c(1 - T_m/T_c)}.$$

By means of equation (4) the values of T_m/T_c for nineteen different substances were calculated and found to equal 0.91.

16. Fundamental correspondences between geometry and thermodynamics. JOHN Q. STEWART, *Princeton University*.—Continuing interpretation of thermodynamics as a physical symbolic logic (Phys. Rev. 34, 1289, (1929), etc.), the following equivalences exist between Euclidean plane geometry and the thermodynamics of reversible systems having two degrees of freedom. The vector corresponds to the working body; its magnitude, r , to volume, v ; x -component to internal energy, U ; y -component to entropy, S ; negative slope, $-m$, to temperature, T . Summing x and y components, respectively, when vectors are added, corresponds to conserving energy and entropy. The Pythagorean relation, $x = (r^2 - y^2)^{1/2}$, expresses the "equation of state" for the Euclidean plane. The corresponding special thermodynamic equation $U = (v^2 - S^2)^{1/2}$, implies reckoning U , v , s , in absolute units, for dimensional equivalence. In general, when U_2 replaces S_1 , and $-S_2$ replaces U_1 , while v remains unchanged, $-1/T_2$ replaces T_1 , and all relations of thermodynamics are preserved. This is on form of Lunn's important "principle of thermodynamic duality." (A. C. Lunn, Phys. Rev. 15, 269 (1920)). Evidently it corresponds to the geometrical symmetry accompanying rotation of axes through $\pi/2$. The general background of these studies is the philosophy of Leibniz. His logic possesses surprisingly close affiliations with thermodynamics.

17. Entropy, elastic strain and the second law of thermodynamics, the principles of least work and of maximum probability. W. S. KIMBALL, *Michigan State College, East Lansing, Michigan*.—By relying on the geometrical expression for weight, $W = N^N(r_1 r_2 \dots r_N)$, and taking strains to include unit extensions in velocity and momentum space as well as ordinary space, a relation is established between entropy and the total strain: $S = kY$, $Y = \log W$, where S is the entropy, k is Boltzmann's constant, Y the total strain and W the *a priori* probability. The Lagrange multiplier method is applied to statically indeterminate frames as well as gas theory, and shows in both cases that the principle of least work, or internal energy, is equivalent to the principle of maximum entropy, probability and strain. Furthermore the equilibrium equations which by the Lagrange method determine the equilibrium state are shown to represent balance between true stress and strain both in gas theory and in the statics of indeterminate frames, revealing the operation in these two domains of the same identical principles (not an analogy). The magnitude of the stress and strain acting in momentum space to maintain equilibrium are calculated for the case of perfect gas at temperature T , the stress being given by $(2\pi e)^{1/2} kT$, and the strain by $(2\pi e)^{1/2} / n$, and the modulus of elasticity is the familiar isothermal bulk modulus p . The outstanding experimental verification of the theory is the second law of thermodynamics. The automatic increases of entropy which it represents are explained as due to increased strain (in momentum space as well as ordinary space) under action of corresponding stresses, rather than as in statistics by the unsatisfactory ergodic hypothesis.

18. Energy changes related to the secondary structure of crystals. F. ZWICKY, *California Inst. of Technology*.—Theoretical considerations have led the author to the postulate of a secondary structure (Π) of large spacing, which is superposed on the primary structure (p) of crystals. According to the theory the Π -atoms are usually more densely packed than the p -atoms. It is $|E_{\pi}| > |E_p|$ where E_{π} and E_p are the respective atomic energies corresponding to the two structures. The p -atoms are therefore more easily removed from the crystal than the Π -atoms. Conditions may be reversed, however, by a plastic deformation inasmuch as this process diminishes $|E_{\pi}|$ into $|E_{\pi}'|$ but does not change E_p . These conclusions lead at once to an understanding of evaporation, etching and certain chemical reaction phenomena involving both perfect and plastically deformed crystals. As a practical criterion of the perfection or imperfection of a lattice the inequalities $|E_{\pi}'| \gtrless |E_p|$ may be used. More detailed considerations are of course required to distinguish crystals of the "metallic" type, which are both macroscopically and microscopically plastic from other types like NaCl which are macroscopically plastic but microscopically brittle. The theory further leads to the interesting conclusion that a voltaic potential difference should be found between Π -planes and p -planes a mounting in general to about 0.001–0.01 volts.

19. An x-ray study of the structure of electrets. MAURICE EWING, *University of Pittsburgh, Erie, Pa.*—Electrets were prepared by allowing a molten mixture of rosin, beeswax, and carnauba wax to solidify in a strong electric field, following Adams (Frank. Inst. J. **204**, 469). These were studied by means of a pinhole camera with filtered characteristic radiation from an x-ray tube having a molybdenum target. The patterns obtained all showed three well-defined rings, which indicated spacing of $3.69 \pm .02\text{\AA}$, $4.15 \pm .02\text{\AA}$, and $4.70 \pm .03\text{\AA}$. The 4.15\AA ring was about three times as intense as the others. When the specimen was set so that the angle between the direction of the x-ray beam and the direction in which the electric field had been applied was zero, each circle was of uniform intensity over its entire circumference; but when this angle was 90° , all circles showed a marked maximum of intensity in the regions in which they would intersect a line drawn through their common center parallel to the direction in which the field had been applied to the specimen.

20. Modified line in scattered x-rays. P. A. ROSS AND J. C. CLARK, *Stanford University*.—With balanced metal foils of silver and palladium in a manner previously described, (Proc. Nat. Acad. Sci. Vol. 9, July 1923; J. A. O. S. Vol. 16, June 1928) an attempt has been made to determine the width and structure of the modified $K\alpha_1$, $K\alpha_2$ lines of antimony scattered from beryllium metal. The differences in transmission between equivalent silver and palladium foils were plotted against scattering angle. With sufficiently narrow slits the differences showed clearly the passage, first of α_2 and then of α_1 past the silver K discontinuity with increasing scattering angle. With present intensity and resolution there is no indication of any step structure or any breadth of line inexplicable by lack of homogeneity of scattering angle in the scattering of antimony $K\alpha_1$, $K\alpha_2$ from beryllium at angles between 55 and 75 degrees.

21. Apparatus for measuring absorption coefficients of soft-x-rays in gases and the absorption in air of the $K\alpha$ line of carbon. ELMER DERSHEM AND MARCEL SCHEIN, *University of Chicago*.—The apparatus consists of an x-ray tube separated by a celluloid window about 2×10^{-4} mm thick from a spectrograph into which gases at various pressures may be introduced. Within the spectrograph beams of different wave-length are isolated by means of a ruled grating. The ratio of the intensity of a given spectral line when the spectrograph is filled with gas at a known pressure to the intensity of the line when the spectrograph is exhausted to a high vacuum is measured by a photographic method. Preliminary results for the mass absorption coefficient (μ/ρ) of air have been obtained for the $K\alpha$ line of carbon ($\lambda = 44.6\text{\AA}$). An average of 76 measures yielded the value $\mu/\rho = 5350 \pm 53$. This probable error of 1 percent compares very favorably with ionization chamber measurements of ordinary x-rays. Extrapolations of any of the various absorption formulae which are known to hold for ordinary x-rays yield values for the absorption coefficients of nitrogen and oxygen which are higher than the above but nevertheless of the same order of magnitude. The investigation is being continued with the use of pure gases and other wave-lengths.

22. Some measurements of currents through the walls of x-ray tubes. DONALD P. LEGALLEY, W. R. HAM, AND MARSH W. WHITE, *Pennsylvania State College*.—The walls of a Coolidge water cooled x-ray tube were coated with a thin layer of tin foil. The potential of this coating was varied from that of the anode, to that of the cathode in about 48 equal steps. With the walls, and the anode of the tube, at the same potential, surprisingly large currents were found to be flowing through the glass to the coating. These amounted to as much as 1 m.a., and 2 m.a. in most cases, but were found to be as large as 3 m.a. in some cases. As the potential of the walls was increased from the anode to the cathode, these currents were found to drop off rapidly, become negative, and fall to zero as soon as full retarding potential was reached. A wide range of tube voltages, and tube currents were used. Coating currents were plotted against retarding potentials, and reproducible curves secured, in which breaks occurred at certain retarding potentials time after time. It was found that the average values of these breaks corresponded to the values of the energy levels (in equivalent volts) of the material used in the anode of the tube.

23. Luminescence due to radioactivity. D. H. KABAKJIAN, *University of Pennsylvania*.—Results of several investigations on the nature and decay of luminescence due to radioactivity carried on under the direction of the author are reviewed. It is shown that the rise and decay of luminescence in various compounds, including phosphorescent zinc sulphide, cannot be explained on Rutherford's theory of "active centres." The observed facts can be explained qualitatively by assuming that the alpha, beta and gamma-rays produce excited molecules in the luminescent material. Return of these molecules to their initial state of more stable equilibrium results in emission of luminous energy. The rate at which this return takes place depends upon the thermal agitation of the molecules. The decay of luminescence is explained as due, not to the destruction of the hypothetical centres, but to the gradual increase of the absorption constant of the material for the light emitted, as evidenced by its discoloration. The disturbances produced by the exciting rays resulting in discoloration are more stable at ordinary room temperatures than those giving rise to luminescence but not necessarily so at higher temperatures. When a compound whose luminescence has decayed is brought to a temperature which removes discoloration it usually recovers its initial brightness.

24. The average life for ionized helium. LOUIS R. MAXWELL, *Bartol Research Foundation*.—The average life $T_{n,l}$ in energy states to ionized helium have been computed for levels up to $n=60$ by calculating all the transition probabilities from the level concerned. The transition probabilities can be obtained directly from known values of the (matrix amplitude)² as evaluated by the eigenfunctions for an electron in a Coulomb field. $T_{n,1}$ was found to increase proportional to n^3 starting with the extremely short time of 1.0×10^{-10} sec. for $n=2$. For other l values this relationship does not always hold but in general $T_{n,l}$ becomes greater for the higher states. T_n (an average mean life l not specified) has the calculated value of 1.3×10^{-10} sec. for $n=2$ which increases to 1.2×10^{-8} sec. for $n=6$. The method for measuring mean lives previously described by the writer (Phys. Rev. 33, 721, (1928)) has been applied to the 4686 series of He II. The displacements were found to become progressively greater in going from the lines 4686 (4→3) and 3203 (5→3) to 2733 (6→3) and to 2511 (7→3). Assuming that the excited helium ion is produced at a single collision then the lines exhibiting the greater shift must represent longer mean lives, which indicates that the average life becomes greater for the outer levels, in agreement with the theory. The above assumption has been substantiated for the line 4686 from intensity-current measurements.

25. The incomplete partial Paschen-Back effect in copper. J. B. GREEN, *Ohio State University*.—The study of the partial Paschen-Back effect in most elements has been limited to the cases in which the multiplet separation is very small compared with the normal Zeeman separation. Darwin has calculated the Zeeman effect for cases in which the magnetic separation varies from 0 to ∞ . His formulas have been applied to Back's measurements on the $^2P^2D$ multiplet of Cu, 5220, 5218, and 5153. These lines, while they show the ordinary characteristics for low fields, have distortions which are due to the small value of the 2D separation 6.90 cm^{-1} compared with the Zeeman splitting 1.74 cm^{-1} . The wave-lengths calculated on Darwin's theory are

in almost complete agreement with experiment. The calculated intensities cannot be compared since the observed intensities are only estimated, but they show qualitative agreement with experiment.

26. Interference measurements in the first spectra of krypton and xenon. C. J. HUMPHREYS, *Bureau of Standards*.—The wave-lengths of the stronger arc lines of krypton and xenon have been redetermined by the use of fixed etalons. The secondary standards of neon, photographed simultaneously with the spectrum under investigation, were used as a comparison. A sufficient number of krypton lines have been examined to permit fixing the relative values of the 1s terms and all the 2p and 3p terms. The accuracy of the term values is such that the average deviation of calculated combinations from the observed wave-numbers is one part in twenty million. The exact location of the combinations in the infrared region not photographically accessible can now be predicted with certainty. Such lines should prove useful wave-length standards for the infrared region. Further work is contemplated in the examination of the lines for hyperfine structure. It is apparent however from the extremely small variations of the term differences that the intensity of any satellites is too low to affect the wave-lengths. For the two strongest lines in the visible krypton spectrum, for which Perard at the International Bureau obtained wave-lengths 5570.2892 and 5870.9154A., we obtain 5570.2890 and 5870.9153A.

27. Spark spectrum of rhodium. A. G. SHENSTONE AND J. J. LIVINGOOD, *Princeton University*.—In the first spark spectrum of rhodium the following terms have been found: for the low structures, $4d^75s$, 5F , 3F , 5P , among the intermediate configurations $4d^75p$, 5F , 5D , 3G , 3F , 3D , 3G , 5D , 5P , 5S . A number of as yet unidentified levels have also been discovered in the low and middle group. The interval rule holds reasonably well for the low 5F and 3F , but not at all for the other multiplets. All are inverted, except the higher 5D from d^7p , which is reinverted, and 5F from the same structure which is partially reinverted. Preliminary investigation of the Zeeman effect indicates that the g-values do not coincide with the Landé predictions. Intensities in the multiplets show the same type of irregularity as occurs in the cobalt spark spectrum.

28. The structure of an emission line. FRANK C. HOYT, *University of Chicago*. The structure of an emission line within the frequency range of its natural width is calculated on the basis of Dirac's radiation theory as modified by Weyl. It is necessary to make use of a solution of the perturbation equations which is valid for a time long compared to the life-time of the excited state, which is in accord with the uncertainty principle. The result obtained is that the spectral distribution is that for a classical oscillator with damping constant $\frac{1}{2}A$, where A is the sum of the probabilities of spontaneous transition from the upper level to all states of lower energy.

29. Absorption and collision broadening of the mercury resonance line. M. W. ZEMANSKY, *National Research Fellow, Princeton University*.—With the assumptions that: (1) the half-breadth of the emission line $\Delta\nu_E$ from a resonance lamp is always greater than that of the absorption line, and depends on the vapor density, geometry, and the exciting line; (2) the half-breadth of the absorption line $\Delta\nu_D$ at low pressures and without any foreign gas is the Doppler breadth; (3) all five components of the $\lambda 2537$ line of mercury are alike both in emission and in absorption;—the absorption for thickness l is calculated as a function of $k(\nu_0)l$ and $\Delta\nu_E/\Delta\nu_D$, where $k(\nu_0)$ is the absorption coefficient for the center of any one of the components. From experimental values, $k(\nu_0)$ is found to be $1.41 \times 10^{-13} N$ where N is the number of atoms per cc. and $\Delta\nu_E/\Delta\nu_D$ is 1.21 in these experiments, 1.6 in Orthmann's, 1.50 in Hughes and Thomas', 1.15 in Kunze's and 1.15 in Kopfermann and Tietze's. The absorption coefficient in the presence of a foreign gas is calculated as a function of the frequency and of $\Delta\nu_C/\Delta\nu_D$ where $\Delta\nu_C$ is the Lorentz collision breadth, and the absorption is calculated as a function of $\Delta\nu_C/\Delta\nu_D$ for the values of $k(\nu_0)l$ and $\Delta\nu_E/\Delta\nu_D$ that hold in these experiments and in those of Orthmann. From experimental values of the absorption of mercury vapor in the presence of H_2 , N_2 , A , and CO , $\Delta\nu_C$ is found as a function of pressure for each gas. From these curves the effective cross-section is found.

30. Energy distribution in the ultraviolet spectrum of skylight. BRIAN O'BRIEN, *J. N. Adam Hospital, Perrysburg, N. Y.*—Energy distribution in the spectrum of sunlight scattered from the sky was measured by a method previously described (Phys. Rev. **33**, 640 (1929)) from $\lambda 4000\text{\AA}$ to $\lambda 2994\text{\AA}$ and compared to energy distribution in the direct solar beam. For very clear sky the ratio of intensity of sky, 90° from sun 60° from zenith, to intensity of sun is proportional to $1/\lambda^4$ over the above wave-length range. For sky uniformly cloudy showing faint blurr of sun, above ratio is nearly independent of λ , and energy distribution in direct solar beam agrees with that measured on very clear days for the same elevation of sun, even when absolute intensity in direct beam is reduced by clouds to $1/100$ that on a clear day. For hazy or slightly cloudy skys ratio of sky intensity to sun intensity increases with decrease in λ but less rapidly than $1/\lambda^4$, the scattering being made up of a molecular and a non-selective term. The values for the energy distribution in the spectrum of direct clear day sunlight $\lambda 3300\text{\AA}$ to $\lambda 2903\text{\AA}$ previously reported, (Phys. Rev. **33**, 1072 (1929)) (J.O.S.A. **20**, 150 (1930)), are thus applicable to sunlight through clouds or haze or scattered by clear or cloudy sky, providing the character of the scattering is taken into account. These results require that both non-selective and molecular scattering occur below the layer of atmospheric ozone, in agreement with accepted values for the height of this layer.

31. Behavior of positive ions in hydrogen. ALLAN C. G. MITCHELL, *Bartol Research Foundation*. In the present experiments, Li or Cs positive ions of various velocities are produced in a tube containing hydrogen molecules. The tube is immersed in liquid air, and the rate of decrease of pressure of hydrogen is measured as a function of the velocity of the positive ions. It is found that with no positive ions entering the tube there is a certain decrease in the pressure of the hydrogen due to its thermal dissociation on the hot filament and its subsequent condensation on the cold walls of the tube. With ions of energies from 15 to 320 volts flowing in the tube the rate of decrease of pressure is greater, showing a formation of some condensable product due to the action of the ions. The rate of pressure decrease with the voltage applied has been found to be proportional to the ion current flowing. The rate per unit current is proportional to the pressure; and the rate per unit current per unit pressure is practically independent of the voltage for Li or Cs ions of energies from 15 to 320 volts. The effect has been shown not to be due to secondary electrons. The number of hydrogen molecules disappearing per positive ion varies from 0.01 to 0.5. No critical voltage at which the effect starts has been found. A detailed account will appear shortly in the Journal of the Franklin Institute.

32. Chemical constitution and association. EUGENE C. BINGHAM AND HOLMES J. FURNWALT, *Lafayette College*. The authors have investigated the fluidities and densities and calculated the associations in several classes of homologous compounds, alcohols, acids, esters, ketones, mercaptans and hydrocarbons. In each case the association decreases as the hydrocarbon chain is increased, but a branched chain lowers the association, and the more, the closer the branch is attached to the middle of the molecule. The association is increased by certain associating groups such as hydroxyl, carboxyl etc. but these are least effective in bringing about association when they are placed at the center of the molecular chain. In the esters the association of different series e.g. the methyl esters, tends toward a definite value as the molecular weight is increased which is of course higher than the value toward which the ethyl esters approach. The association in excess of this minimum of any methyl ester has been found to be lowered quite precisely 46 percent by the addition of the methylene group necessary in going to the next higher member of the series. A recent note in Science indicated that for fifty-seven compounds the average deviation between the observed and calculated values is 0.9 percent.

33. The diffraction of hydrogen atoms. THOMAS H. JOHNSON, *Bartol Research Foundation*. The diffraction patterns which are formed when a very fine circular beam of hydrogen atoms is reflected from a cleaved 100 surface of a crystal of lithium fluoride have been photographed on a molybdenum oxide plate. Various arrangements of the crystal and plate were used. At normal incidence, with the plate perpendicular to the specularly reflected beam, the pattern consisted of two lines intersecting at right angles in the specular beam. These lines were parallel to the rows of similar ions on the surface of the crystal. The patterns for other

angles of incidence in both the 110 plane and the 100 plane have also been photographed and in each case the pattern is a set of conic sections which satisfy the two crossed grating formulae, $\cos\theta_0 - \cos\theta = n\lambda/d$; $\cos\phi_0 - \cos\phi = m\lambda/d$, where θ and ϕ are the angles between the beam and the two sets of lines of similar ions on the surface. The patterns observed correspond to $m=0$, $n=1$ and to $n=0$, $m=1$. The positions of maximum intensity correspond well with the calculated angles for the most probable wave-length in the Maxwellian distribution, if the wave-length is calculated from the velocity by the de Broglie formula, $\lambda = h/mv$.

THE PHYSICAL REVIEW

THE FINE STRUCTURE OF He AS A TEST OF THE SPIN INTERACTIONS OF TWO ELECTRONS

BY G. BREIT

DEPARTMENT OF PHYSICS, NEW YORK UNIVERSITY

(Received June 16, 1930)

ABSTRACT

A tentative expression for the quantum Hamiltonian of two electrons has been set up in a previous paper. The equation is discussed again. It is shown that the last term in it is subject to doubt. The Hamiltonian is tested by applying it to the calculation of the fine structure of the $\text{He } 2^3P$ level. It is found that the above mentioned term in e^4 is in contradiction with experiment. Removing the term from the equation one is left essentially with Heisenberg's old Hamiltonian. The spin interaction in it is shown to agree well with experiment. The calculation has been applied also to Li^+ .

The essential improvements on previous work are: (1) an increase in the precision of the unperturbed eigenfunctions; (2) a determination from experimental data of a constant D which depends directly on spin—spin interactions (see Eq. (1) below) and which can be calculated with fair accuracy. Comparing the theoretical and empirical values of D a clearer test of the magnitude of spin—spin interactions can be obtained than by calculating the relative positions of the three components of the triplet. The reason for this is that the relative positions of the lines depend also on another constant C which is a difference of two approximately equal numbers and is more difficult to calculate accurately.

§I PURPOSE OF WORK AND RESULTS

THE motion of one electron in an external field is treated very satisfactorily by the Dirac equation. It is desirable to have a similar treatment of the two or many electron problem. A partial attempt in this direction has been made by the writer.¹ Considerations in configuration space and also the application of the Heisenberg-Pauli² wave field theory led to the Eq. (6) of the above paper. This equation appeared at the time as a likely one, but it was impossible to give a rigorous derivation. The writer has used the first form of the Heisenberg-Pauli theory. Because of the indefiniteness due to the infinite self interactions of point charges with themselves a certain amount of

¹ Breit, Phys. Rev. **34**, 553 (1929).

² W. Heisenberg and W. Pauli Jr., Zeits. f. Physik **56**, 1, 1929, Zeits. f. Physik **59**, 168 (1930).

arbitrariness was necessary in removing the infinite terms of the total energy. Also the interaction was derived only to the first approximation in e^2 . The same problem has been treated in more detail by Oppenheimer³ who showed that even to higher powers of e^2 the writer's Eq. (6) could be derived if certain infinite terms of the interaction energy are systematically neglected. However, Oppenheimer also shows that a strict application of the wave field theory leads to infinite relative displacements of the atomic energy levels. The failure of quantum mechanics to give a satisfactory account of the electromagnetic interaction of two particles appears to be connected with two difficult questions: (1) the size of the electron i.e. whether the electron can be located at a point and (2) the Dirac jumps to states of negative energy which make it impossible to have normal states for a finite number of particles. Neither of these questions can be answered at present and it seems that no satisfactory purely theoretical solution of the two electron problem can be obtained before this is done.

The derivation of (6) in configuration space was obtained by using Darwin's classical Hamiltonian function. The choice of quantum symbols has been made in such a way as to obtain equations of motion in agreement with the classical ones. This however was not sufficient to establish the validity of the equation. In fact a discussion in configuration space enables one to see a fault in the equation. In order to explain this unsatisfactory feature we explain first in somewhat more detail the satisfactory side of it. With (6) as it stands we have, omitting the external field, the following equations of motion:

$$(A) \quad \dot{x}_k^I = -c\alpha_k^I; \quad \dot{p}_k^I = -e_I e_{II} \frac{\partial}{\partial x_k^I} \left\{ r^{-1} - \frac{1}{2} [(\mathbf{a}^I \mathbf{a}^{II}) r^{-1} + r^{-3} (\mathbf{a}^I \mathbf{r})(\mathbf{a}^{II} \mathbf{r})] \right\}$$

The classical expressions obtained from Darwin's Hamiltonian are:

$$(B) \quad \dot{x}_k^I = v_k = \frac{p_k^I}{m_I} - \frac{p_k^I p_I^2}{2c^2 m_I^3} - \frac{e_I e_{II}}{2m_I m_{II} c^2} [p_k^{II} r^{-1} + r^{-3} (x_k^{II} - x_k^I)(p_{II} \mathbf{r})]$$

$$(C) \quad \dot{p}_k^I = -e_I e_{II} \frac{\partial}{\partial x_k^I} \{ r^{-1} - (1/2m_I m_{II} c^2) [r^{-1} (\mathbf{p}^I \mathbf{p}^{II}) + r^{-3} (\mathbf{p}^I \mathbf{r})(\mathbf{p}^{II} \mathbf{r})] \}.$$

The first equation (A) is an exact relation between the velocity and α_k . Equation (B) connects the velocities with the momenta. It was supposed that, in the sense of the correspondence principle, (B) is also true in the quantum theory. It then followed that (C) agrees with the second equation (A) to within terms in $(v/c)^2$. The p_k^I of Eq. (6) therefore replaces Darwin's \dot{p}_k^I because they have the same rate of change. The employment of equation (B) in the quantum theory is, of course, questionable. All that can be said is that the correct quantum equation should give (B) as an effective equation holding for wave packages. This has to be proved for whatever equation is finally devised.

³ J. R. Oppenheimer, Phys. Rev. 35, 461 (1930).

For the discussion of positive energy levels we can use the writer's Eq. (48) which is equivalent to (6). Here if terms in \hbar are dropped the Hamiltonian becomes exactly the classical one with the exception that the last term does not disappear. This shows that (B) and (C) are not satisfied consistently in Eq. (6) the error being of the order of e^4/mc^2r^2 . The writer is very grateful to Professors Pauli and Heisenberg for emphasizing the fact that this last term does not contain \hbar .

There is another unsatisfactory property of Eq. (6). Equation (B) gives p_k^I, p_k^{II} in terms of v_k^I, v_k^{II} . Thus

$$\mathbf{p}_I = m_I \mathbf{v}_I + m_I \mathbf{v}_I (v_I^2/2c^2) + (e_I e_{II}/2c^2) [r^{-1} \mathbf{v}_{II} + r^{-3} \mathbf{r} (\mathbf{v}_{II} \cdot \mathbf{r})]$$

This is a purely classical relation. In (6) \mathbf{p}_I is replaced by $(\hbar/2\pi i) \nabla_I$. For a single particle of charge e_I in an external field of vector potential \mathbf{A}_I we replace $m_I \mathbf{v}_I (1 - \beta_I^2)^{-1/2}$ by $(\hbar/2\pi i) \nabla_I - (e_I/c) \mathbf{A}_I$. In this case, to a sufficient approximation $\mathbf{A}_I = e_{II} \mathbf{v}_{II}/cr$. We should expect that a correct theory will replace $m_I \mathbf{v}_I (1 - \beta_I^2)^{-1/2} \cong m_I \mathbf{v}_I + m_I \mathbf{v}_I (v_I^2/2c^2)$ by $\mathbf{p}_I - (e_I e_{II} \mathbf{v}_{II}/c^2 r)$. We have identified however the quantum operator $(\hbar/2\pi i) \nabla_I$ with Darwin's \mathbf{p}_I . We see therefore that \mathbf{p}_I in (6) replaces the classical

$$\left[\frac{m_I \mathbf{v}_I}{(1 - \beta_I^2)^{1/2}} + \frac{e_I e_{II} \mathbf{v}_{II}}{c^2 r} \right] + \frac{e_I e_{II}}{2c^2} \left[-\frac{\mathbf{v}_{II}}{r} + \frac{\mathbf{r} (\mathbf{v}_{II} \cdot \mathbf{r})}{r^3} \right]$$

while it would be more satisfactory if it replaced only the first part of that expression. This means that if m_{II} becomes very large and the reaction on particle II negligible there is no exact agreement between (6) and Dirac's equation. It is thus seen that (6) is likely to be right only to the first order in e^2 . Also from the point of view of the wave field theory there is much less arbitrariness in the derivation of first order effects in e^2 .

With Eq. (6) it is possible to derive an equation involving two row, two column spin matrices and showing therefore the interaction of electrons as a function of their spins. This is Eq. (48). The interaction energy contains, in addition to the ordinary spin interactions, the extra term in e^4 . It is seen from the above considerations that the presence of this term is subject to doubt. In the writer's previous paper it has been supposed that the term might have a physical significance. Some rough estimates of the order of magnitude of its effect indicated that it might be reconcilable with experimental facts. It was felt however that a more accurate test is needed.

A possibility of testing the spin interaction in e^4 is offered by the fine structure of the He triplet spectrum and to some extent by that of Li^+ . It has been shown by Heisenberg⁴ that the inverted positions of the triplet components in these spectra can be explained by taking into account the interaction of electron spins with each other. The magnitude of the separations was also shown by him to be approximately in agreement with experiment. An attempt to refine Heisenberg's calculation has been made by Sugiura.⁵

⁴ Heisenberg, Zeits. f. Physik **39**, 499 (1926).

⁵ Sugiura, Zeits. f. Physik **44**, 190 (1927).

He considered in an approximate way the effect of polarization of the charge distribution formed by the inner electron due to the electric field of the outer one. A somewhat better agreement with the total separation in the yellow He has been obtained by using this correction. Gaunt⁶ has also attempted to improve on Heisenberg's calculation but has not reached a definite conclusion. The difficulty in the application of Gaunt's calculation lies in the insufficiently accurate unperturbed eigenfunctions used by him.

In the present paper the effect of all the spin interactions is calculated using unperturbed eigenfunctions determined by the variational equation derived in the writer's recent paper.⁷ These functions are also not exact but they are more accurate than those previously used. The result of the calculation is that satisfactory agreement with the experimentally observed fine structure is obtained if the extra terms in e^4 are neglected. The agreement with experiment is spoiled if the supposed additional effect of these terms is taken into account. This conclusion follows from the fine structure of He and to some extent also from the fine structure of Li^+ if the recent interpretation of the hyperfine structure of that spectrum is adopted.⁸ The conclusion is therefore that the terms in e^4 have no physical significance and that Eq. (6) is not correct to higher orders than e^2 . With terms of the first order in e^2 satisfactory agreement with experiment is obtained.

The present test is not able to distinguish between Gaunt's equation or Eq. (6) with the terms in e^4 omitted. Both of these agree with the observed fine structure. It is hard to believe however that the terms in $(1/2r)[(\mathbf{p}^I\mathbf{p}^{II}) + (\mathbf{p}^Ir)(\mathbf{p}^{II}r)/r^2]$ do not exist and are replaced by $(\mathbf{p}^I\mathbf{p}^{II})/r$. For this reason Gaunt's equation is also very likely to be incorrect. Further, Eq. (36) of the writer's previous paper is equivalent to Gaunt's and is seen also to contain terms in e^4 . These terms do not have any influence on the fine structure being of the form $(e^4/4mc^2r^2)(3 - 2(\sigma^I\sigma^{II}))$. They cannot have a physical significance since they do not vanish if $\hbar \rightarrow 0$.

The calculations which follow are rather laborious and it is advisable to explain at this point the comparison of the results with the experimental fine structure. The effect of spin interactions is taken into account by the ordinary method of perturbation calculations. Both in He and Li^+ this method should give, in the first order, results much more accurate than the experimental precision. This is seen directly from the fact that the separations in the fine structure are of the order of a few cm^{-1} while the total term value is of the order of $2 \times 10^4 \text{ cm}^{-1}$. In the perturbation calculation the effect of the spins is first of all neglected and the eigenfunctions used are determined. Their form is that of (21) in the writer's previous paper.⁷ Quite independently of the form of the function F it may be shown that the relative position of the three components of a triplet P term is given to the first order of the spin perturbations (and therefore very accurately in our case) by the following expression for the energy

$$E = E_0 + [-3(C + D), 2(D - C), 0] \quad (1)$$

for $j = 0, 1, 2$

where j is the inner quantum number, and C, D are certain integrals in terms of F . The term C is due to the interaction of the electric field with the electron spins. It is this term that gives rise to the ordinary multiplet structure and commonly goes under the name of the interaction of the spin with orbital angular momentum. By itself (i.e. neglecting D) it would give rise to the Landé interval rule. Although there are at present no accurate quantitative confirmations of the correctness of C , there appears to be no reason for doubting it particularly on account of the large number of cases which are in qualitative agreement and it is therefore supposed that the physical nature of C is correct. The integral D however involves the interactions of the two electronic spins with each other in the form of $f(r) (\sigma_1 \mathbf{r}) (\sigma_2 \mathbf{r})$.⁹ The questionable terms in e^4 give rise to a part of D which will be called D_1 , while the terms in e^2 give rise to another part D_0 .

$$D = D_0 + D_1 \text{ with terms in } e^4 \quad (2)$$

$$\text{or } D = D_0 \text{ without terms in } e^4$$

The experimentally known fine structure determines from (1) both $C+D$ and $C-D$, and therefore also C and D . These values will be called *empirical* values of C and D . The comparison with experiment is made by computing D according to the first and the second Eq. (2). It is found that the first equation is in disagreement with the empirical value of D while the second agrees well with it. This agreement does not appear to be accidental because D_0 consists mainly of terms of the same sign and also because the agreement holds in He and Li^+ .¹⁰

Since the physical nature of C appears to be sound this constant has been used as a check on the accuracy of the approximate form of F . It has proved difficult to obtain absolute agreement of the empirical and theoretical values of C . The difficulty lies in the laboriousness of the determination of eigenfunctions by the variational method and particularly in the fact that C is a difference of two numbers which are of approximately the same magnitude. These two approximately equal but opposite contributions to C are due to (1) the electric field of the nucleus acting on the spin of each electron and (2) the electric field of one electron acting on the spin of the other. The latter of these two effects turns out to be the larger one numerically. It depends essentially on the average value of $1/r^3$. From the agreement of the empirical and theoretical values of C it is possible to estimate the accuracy of the second part of C . The constant D_0 also depends essentially on $1/r^3$. The estimated accuracy of the second part of C gives one therefore a guide as to the accuracy of the computation for D_0 .

⁹ r is written here and later for the distance between the two electrons. The two electrons are referred to from now on as 1 and 2 rather than I and II.

¹⁰ The numerical calculations on Li^+ were made jointly with Mr. L. P. Granath of this

For He the result of the calculation is

$$(C, D_0, D_1) = (R_H \alpha^2 / 24) (-0.91, -0.62, +0.27) \quad (3)$$

where R_H is the Rydberg constant for hydrogen and α is the fine structure constant. In comparing this with empirical material we find somewhat different data. The results of Houston¹¹ and of Hansen¹² agree in giving $\Delta\nu_{02}/\Delta\nu_{12} = 14$ with $\Delta\nu_{02} = -3(C+D) = 1.068 \text{ cm}^{-1}$; $\Delta\nu_{12} = -2(C-D) = 0.077 \text{ cm}^{-1}$. The results of Wei¹³ are somewhat different giving $\Delta\nu_{02}/\Delta\nu_{12} = 10$ or 11. With the results of Hansen and Houston the empirical value of D is $(R_H \alpha^2 / 24) (-0.65) \text{ cm}^{-1}$ while using the results of Wei it is $(R_H \alpha^2 / 24) (-0.60) \text{ cm}^{-1}$. Either of these values is in good agreement with D_0 and is definitely in disagreement with $D_0 + D_1$. From the Hansen, Houston data we obtain as the empirical value of $C = -(R_H \alpha^2 / 24) 0.81$. This is not in very good agreement with the computed value listed in (3). However the agreement is as good as can be expected. This may be seen by considering the numerical part of the calculation for C . In the final step of the calculation we have $C = 1.302 R_H (\alpha^2 / 24) (1.020 - 1.719)$. The first of these numbers 1.020 is due to the action of the electric field of the nucleus and the second -1.719 is due to the field of the electrons. An error of 5% in the second number is likely to be accompanied by an approximately equal error in the opposite direction for the first number because the eigenfunction is normalized. An error of 10% in 1.719 is 0.17 and this constitutes an error of 24% in the result $-0.70 = 1.02 - 1.72$. It is therefore likely that the disagreement of 12% between the computed and the empirical value of C is an indication of an accuracy of about 2.5% in the computation of either the first or the second part of it. In other words the apparently low accuracy is due to the fact that C is the difference of two parts which are approximately equal in numerical magnitude. Using Wei's value for the separation ratio $C = -(R_H \alpha^2 / 24) (0.84)$. If this value is right the computation for C is correct to 8.3% and a likely accuracy of the calculation of each part is 1.7%. For Wei's value of the separation ratio the empirical values of both C and D come out lower than the calculated by consistent amounts. Using Houston and Hansen's observations the empirical D is higher than the calculated and the empirical C is lower. This is somewhat inconsistent because the error in the calculation is likely to be such as to overestimate the square of the eigenfunction for low r . It is likely however that neither the experiment nor the calculation is accurate enough to decide this point. It is only clear that the computed D_0 agrees well with either set of data and that the computed C , although different from the empirical, does not differ from it by more than can be explained by reasonable errors in the calculation. The presence of D_1 is definitely excluded since it would imply an inaccuracy of 43% in the calculation of D_0 . The value of the nuclear spin is immaterial for the present application.

laboratory and the writer is very grateful to him for his permission to quote here the results.

§II DETERMINATION OF APPROXIMATE UNPERTURBED FUNCTIONS

It has been shown by the writer⁷ that 3P states of a two electron configuration involving two electronic states with unequal azimuthal quantum numbers have the following complete set of normal orthogonal eigenfunctions

$$\begin{aligned} u_1 &= (3^{1/2}/4\pi)(F \sin \theta_1 e^{i\phi_1} - \tilde{F} \sin \theta_2 e^{i\phi_2}) \\ u_0 &= (6^{1/2}/4\pi)(F \cos \theta_1 - \tilde{F} \cos \theta_2) \\ u_{-1} &= (3^{1/2}/4\pi)(F \sin \theta_1 e^{-i\phi_1} - \tilde{F} \sin \theta_2 e^{-i\phi_2}) \end{aligned} \quad (4)$$

$$F = F(r_1, r_2; \theta), \tilde{F} = F(r_2, r_1; \theta)$$

where (r_1, θ_1, ϕ_1) , (r_2, θ_2, ϕ_2) are polar coordinates for each electron and $\cos \theta = \cos \theta_1 \cos \theta_2 + \sin \theta_1 \sin \theta_2 \cos(\phi_2 - \phi_1)$ so that θ is the angle between r_1, r_2 . This form is exact as long as the spin interactions are not brought in. If we had the exact form of F the whole problem could be solved quite accurately because as has been explained in §1 the first order of the perturbation calculation for the effect of spins should give a result of much higher accuracy than that of the experimental determinations. Unfortunately it is very difficult to determine F precisely and it is more practical to use good approximations for its form. Again, without approximations F is determined by the following conditions

$$\begin{aligned} \delta \int \left\{ \sum_{i=1,2} \left[\left(\frac{\partial F}{\partial r_i} \right)^2 - 2 \cos \theta \frac{\partial F}{\partial r_i} \frac{\partial \tilde{F}}{\partial r_i} + \left(\frac{\partial \tilde{F}}{\partial r_i} \right)^2 \right] + 2F^2/r_1^2 + 2\tilde{F}^2/r_2^2 \right. \\ \left. + 2 \sin \theta F \frac{\partial \tilde{F}}{r_1^2 \partial \theta} + 2 \sin \theta \tilde{F} \frac{\partial F}{r_2^2 \partial \theta} + \left(\frac{1}{r_1^2} + \frac{1}{r_2^2} \right) \left[\left(\frac{\partial F}{\partial \theta} \right)^2 - 2 \cos \theta \frac{\partial F}{\partial \theta} \frac{\partial \tilde{F}}{\partial \theta} + \left(\frac{\partial \tilde{F}}{\partial \theta} \right)^2 \right] \right. \\ \left. + (8\pi^2 m/h^2)(V - E)(F^2 - 2F\tilde{F} \cos \theta + \tilde{F}^2) \right\} dV = 0 \end{aligned}$$

$$dV = r_1^2 r_2^2 \sin \theta dr_1 dr_2 d\theta \quad (4)$$

with the normalization condition

$$\int (F^2 - 2F\tilde{F} \cos \theta + \tilde{F}^2) dV = 1. \quad (5)$$

The ranges of integration are here $0 < r_1 < \infty$, $0 < r_2 < \infty$, $0 < \theta < \pi$. In order to determine F precisely it would be sufficient to expand it in the form of a sum of a complete set of orthogonal functions with arbitrary coefficients and then to determine the coefficients by means of (4) and (5). Since the labor involved in this is very great and since the resultant series must subsequently be used in the perturbation calculation an approximate solution of the problem has been obtained by the current variety of the Ritz method. It has been supposed that to a sufficient approximation

$$F = r_1(1 + c \cos \theta) \exp[-ar_1/2 - br_2/2]. \quad (6)$$

This form is suggested by the usual screening considerations. The first electron (1) can be thought of approximately as moving in a screened field force subject to a potential $(Z-1)/e^2r$ while the second electron (2) is moving mainly in an unscreened field Ze^2/r . If this is supposed to be true then it is found that (1) is actually likely to be found outside of the region where there is a large probability of finding (2). Approximately therefore the radial part of (6) should give the solution. It is this kind of approximation that has been used by Gaunt with values of a, b derived directly by the screening considerations. This consideration is not exact and it can be improved by introducing the dependence on c and adjusting a, b, c so that (4), (5) are satisfied. The improvement to be expected from using (6) with adjustable constants amounts essentially to correcting the field of force acting on (1) for the incomplete screening of the nucleus by (2) and also to taking into account the fact that the two electrons cannot be considered as distributed on spherical shells and that the probability of a configuration r_1, r_2, θ depends on θ . We let

$$\begin{aligned} A_{r_i} &= \left(\frac{\partial F}{\partial r_i} \right)^2 - 2\mu \frac{\partial F}{\partial r_i} \frac{\partial \tilde{F}}{\partial r_i} + \left(\frac{\partial \tilde{F}}{\partial r_i} \right)^2; \mu = \cos \theta \\ A_\theta &= \left[\left(\frac{\partial F}{\partial \theta} \right)^2 - 2\mu \frac{\partial F}{\partial \theta} \frac{\partial \tilde{F}}{\partial \theta} + \left(\frac{\partial \tilde{F}}{\partial \theta} \right)^2 \right] (r_1^{-2} + r_2^{-2}). \\ B_\theta &= 2r_1^{-2}F^2 + 2r_2^{-2}\tilde{F}^2 + 2r_1^{-2} \sin \theta F \frac{\partial F}{\partial \theta} + 2r_2^{-2} \sin \theta \tilde{F} \frac{\partial \tilde{F}}{\partial \theta}. \end{aligned} \quad (7)$$

Substituting (6) and performing integrations involving only simple exponentials we find:

$$\begin{aligned} \int A_{r_i} dV &= (1 + c^2/3)(8a^{-3}b^{-3} + 24a^{-5}b^{-1}) + bc(16\beta^{-7} - 24a\beta^{-8}); \quad 2\beta = a + b \\ \int B_\theta dV &= 32a^{-3}b^{-3}(1 + c^2/3) - 32c\beta^{-6}; \quad \int A_\theta dV = (c^2/3)(192a^{-5}b^{-1} + 32a^{-3}b^{-3}) \\ \int (r_1^{-1} + r_2^{-1})(F^2 - 2\mu F\tilde{F} + \tilde{F}^2) dV &= (1 + c^2/3)(48a^{-4}b^{-3} + 96a^{-5}b^{-2}) - 64c\beta^{-7} \\ \int (F^2 - 2\mu F\tilde{F} + \tilde{F}^2) dV &= 192[(1 + c^2/3)a^{-5}b^{-3} - (c/2)\beta^{-8}]. \end{aligned} \quad (9)$$

The integrations involving r^{-1} are somewhat more complicated. Expanding r^{-1} in zonal harmonics and powers of r_1, r_2 , and then using¹⁴

$$\int_{-1}^{+1} \mu^n P_m(\mu) d\mu = \frac{2^{m+1}n!}{(n+m+1)!} \frac{\left(\frac{n}{2} + \frac{m}{2}\right)!}{\left(\frac{n}{2} - \frac{m}{2}\right)!} \quad (n \geq m) \quad (10)$$

¹⁴ Whittaker and Watson, *Modern Analysis*, p. 311.

we have

$$\begin{aligned} \int_{-1}^{+1} (1 + c\mu)^2 r^{-1} d\mu &= 2(1 + c^2/3)\rho_1^{-1} + (4c/3)\rho_2\rho_1^{-2} + (4c^2/15)\rho_2^2\rho_1^{-3} \\ \int_{-1}^{+1} \mu(1 + c\mu)^2 r^{-1} d\mu &= (4c/3)\rho_1^{-1} + (2/3 + 2c^2/5)\rho_2\rho_1^{-2} \\ &+ (8c/15)\rho_2^2\rho_1^{-3} + (4c^2/35)\rho_2^3\rho_1^{-4} \end{aligned} \quad (11)$$

with the convention

$$r_1, r_2 = \rho_1, \rho_2 \text{ if } r_1 < r_2; r_1, r_2 = \rho_2, \rho_1 \text{ if } r_1 > r_2$$

Using

$$\begin{aligned} \int \int_{r_1 > r_2} \exp(-ar_1 - br_2) dr_1 dr_2 &= a^{-1}(a+b)^{-1}, \\ \int \int_{r_1 < r_2} \exp(-ar_1 - br_2) dr_1 dr_2 &= b^{-1}(a+b)^{-1} \end{aligned} \quad (12)$$

we derive by successive differentiations with respect to a, b

$$\int_0^\infty \int_0^\infty r_1^2 r_2^2 \rho_1^{-1} \exp(-ar_1 - br_2) dr_1 dr_2 = 2[a^{-2}b^{-2}(a+b)^{-1} + a^{-1}b^{-1}(a+b)^{-3}] \quad (13)$$

Again using (12)

$$\int_0^\infty \int_0^\infty r_1^2 r_2^2 \rho_2 \rho_1^{-2} \exp(-ar_1 - br_2) dr_1 dr_2 = 6/[ab(a+b)^3].$$

Integrating (12) with respect to a and using

$$\int_0^\infty r^{-1} [\exp(-ar) - \exp(-(a+b)r)] dr = \log(1+b/a)$$

we get

$$\begin{aligned} \int_0^\infty \int_0^\infty r_1^2 r_2^2 \rho_2^2 \rho_1^{-3} \exp(-ar_1 - br_2) dr_1 dr_2 &= 24a^{-5} \log(1+a/b) \\ &+ 24b^{-5} \log(1+b/a) - 24(a^{-4} + b^{-4})(a+b)^{-1} - 12(a+b)^{-2}(a^{-3} + b^{-3}) \\ &- 8(a+b)^{-3}(a^{-2} + b^{-2}) - 6(a+b)^{-4}(a^{-1} + b^{-1}). \end{aligned} \quad (15)$$

Using (11), (13), (14), (15) one part of the integral involving r^{-1} is evaluated as

$$\begin{aligned} \int F^2 r^{-1} dV &= \frac{\partial^2}{\partial a^2} \int (1 + c\mu)^2 r^{-1} \exp(-ar_1 - br_2) dV = \frac{24}{ab(a+b)^2} \left[\frac{2a+b}{a^3b} + \right. \\ &\left. \frac{3a+b}{a(a+b)^3} \right] + c \left[\frac{16}{a^3b(a+b)^3} + \frac{48}{a^2b(a+b)^4} + \frac{96}{ab(a+b)^5} \right] + c^2 \left[192a^{-7} \log \right. \\ &\left. \frac{a+b}{b} - \frac{192}{a^6(a+b)} - \frac{96}{a^5(a+b)^2} + \frac{32}{5b^4a^2(a+b)} + \frac{32}{5b^4a(a+b)^2} \right] \end{aligned} \quad (16)$$

$$-\frac{56a^{-4} + (64/5)b^{-4}}{(a+b)^3} - \frac{24a^{-3} + (96/5)b^{-3}}{(a+b)^4} + \frac{48(a^{-2} - b^{-2})}{5(a+b)^5} + \frac{48(a^{-1} + b^{-1})}{(a+b)^5} \Big]$$

Another part of the integral in r^{-1} is given by the second line of (11). Using (12) we find

$$\begin{aligned} \frac{1}{2} \int_0^\infty \int_0^\infty r_1^3 r_2^3 \rho_2^3 \rho_1^{-4} \exp[-\beta(r_1 + r_2)] dr_1 dr_2 &= (720 \log 2 - 497.625) \beta^{-7} \\ \frac{1}{2} \int_0^\infty \int_0^\infty r_1^3 r_2^3 \rho_2^2 \rho_1^{-3} \exp[-\beta(r_1 + r_2)] dr_1 dr_2 &= (15/8) \beta^{-7} \\ \frac{1}{2} \int_0^\infty \int_0^\infty r_1^3 r_2^3 \rho_2 \rho_1^{-2} \exp[-\beta(r_1 + r_2)] dr_1 dr_2 &= (21/8) \beta^{-7} \\ \frac{1}{2} \int_0^\infty \int_0^\infty r_1^3 r_2^3 \rho_1^{-1} \exp[-\beta(r_1 + r_2)] dr_1 dr_2 &= (33/8) \beta^{-7}. \end{aligned} \quad (17)$$

Substituting these expressions (17) into the second line of (11) it is found that

$$\int \mu F \tilde{F} r^{-1} dV = \{3.5 + 13c + [2.1 + (8/35)(720 \log 2 - 497.625)]c^2\} \beta^{-7} \quad (18)$$

Combining (16) and (18) we also have $\int r^{-1}(F^2 - 2\mu F \tilde{F} + \tilde{F}^2) dV$. The variational Eq. (4) with the restricting condition (5) is now obtained by using (8), (9), (16), (18). On performing the substitutions it is convenient to use dimensionless variables x, y defined by

$$a = \alpha G, \quad b = \gamma G, \quad G = 8\pi^2 m Z e^2 / \hbar^2. \quad (19)$$

The constant G is related to the Rydberg constant by

$$4R_Z = GZ e^2. \quad (20)$$

The variational Eq. (4) becomes equivalent to the requirement that the fraction

$$\frac{E}{R_Z} = \frac{\alpha_0 + 2\alpha_1 c + \alpha_2 c^2}{\beta_0 + 2\beta_1 c + \beta_2 c^2} \quad (21)$$

should become a minimum. Here

$$\begin{aligned} \alpha_0 &= x^2 + y^2 - x - 2y + \frac{x}{Z} \left[\frac{x^2 y^2}{(x+y)^2} \left\{ \frac{2x+y}{x^2 y} + \frac{3x+y}{(x+y)^3} \right\} - \frac{56x^4 y^3}{3(x+y)^7} \right] \\ 2\alpha_1 &= x^5 y^3 \left\{ \frac{256y}{3(x+y)^7} - \frac{256xy}{(x+y)^8} - \frac{128}{3(x+y)^6} + \frac{512}{3(x+y)^7} \right. \\ &\quad \left. + \frac{2}{Z} \left[\frac{1}{3x^3 y(x+y)^3} + \frac{1}{x^2 y(x+y)^4} + \frac{2}{xy(x+y)^5} - \frac{104}{3(x+y)^7} \right] \right\} \\ \alpha_2 &= (5/3)y^2 + (5/9)x^2 - x/3 - 2y/3 + \frac{2}{Z} [x^5 y^3 (\zeta/180) - 6.48x^5 y^3 (x+y)^{-7}] \end{aligned} \quad (22)$$

$$\begin{aligned} \beta_0 &= 1, \quad 2\beta_1 = -128x^5y^3(x+y)^{-8}, \quad \beta_2 = 1/3 \\ \zeta &= 720x^{-7} \log(1+x/y) - 720x^{-6}(x+y)^{-1} - 360x^{-5}(x+y)^{-2} \\ &\quad + 24x^{-2}y^{-4}(x+y)^{-1} + 24x^{-1}y^{-4}(x+y)^{-2} - (210x^{-4} + 48y^{-4})(x+y)^{-3} \\ &\quad - (90x^{-3} + 72y^{-3})(x+y)^{-4} + 36(x^{-2} - y^{-2})(x+y)^{-5} + 180x^{-1}(x+y)^{-6} \\ &\quad + 180y^{-1}(x+y)^{-6}. \end{aligned} \quad (23)$$

The number 6.48 in the last term α_2 is the approximate value of $(32/15) [(21/8) + (2/7) (720 \log 2 - 497.625)]$. The result of minimizing (21) is¹⁵

$$x = 0.273, \quad y = 1.00 \quad c = -0.0089 \quad (25)$$

and the value of E/R_z corresponding to this is

$$E/R_z = -1.0654$$

while the experimental value is

$$(E/R_z)_{exp} = -1.0666.$$

Of the three constants entering the eigenfunction the constant x is the most important one for the following computations because it determines the mean radius of the outer electron and enters as a factor x^3 in most of the important terms of the formulas for fine structure separations. It should be observed here that the eigenfunction is sufficiently exact to determine the energy value to 0.1% which is a higher order of accuracy than that aimed at in the calculation of the fine structure.

§III SECULAR EQUATION FOR FINE STRUCTURE

Denoting, as is customary, the electronic spin functions by S_α, S_β with $S_\alpha = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, S_\beta = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$ we have a system of three normal orthogonal linearly independent functions

$$S_1 = S_\alpha^1 S_\alpha^2, \quad S_0 = 2^{-1/2}(S_\alpha^1 S_\beta^2 + S_\alpha^2 S_\beta^1), \quad S_{-1} = S_\beta^1 S_\beta^2 \quad (26)$$

the upper indices referring to the two electrons. These three functions when combined with the three coordinate functions (4) form a complete set of normal orthogonal functions of an unperturbed 3P state. The system may be arranged in a table as follows

m				
2	$u_1 S_1$			
1	$u_1 S_0$	$u_0 S_1$		
0	$u_1 S_{-1}$	$u_0 S_0$	$u_{-1} S_1$	
-1		$u_0 S_{-1}$	$u_{-1} S_0$	
-2			$u_{-1} S_{-1}$	

(27)

¹⁵ Dr. R. W. G. Wyckoff of the Rockefeller Institute has performed most of the numerical calculations on a calculating machine. The writer is very grateful to him for this assistance.

each row corresponding to a fixed magnetic quantum number m . The perturbation energy¹⁵ is

$$\Delta H = A\delta_1 + B\delta_2 + \mathcal{D}_0 + \mathcal{D}_1 \quad (28)$$

with

$$A = \frac{he^2}{8\pi m^2 c^2} \{ Zr_1^{-3} \mathbf{M}_1 + r^{-3} [(\mathbf{r}_1 - \mathbf{r}_2) \times (2\mathbf{p}_2 - \mathbf{p}_1)] \} \quad (28')$$

$$B = \frac{he^2}{8\pi m^2 c^2} \{ Zr_2^{-3} \mathbf{M}_2 + r^{-3} [(\mathbf{r}_2 - \mathbf{r}_1) \times (2\mathbf{p}_1 - \mathbf{p}_2)] \} \quad (28'')$$

$$\mathcal{D}_0 = R_0(r)(\delta_1 \mathbf{r})(\delta_2 \mathbf{r}), \quad R_0(r) = -(eh/4\pi mc)^2 3r^{-5} \quad (28''')$$

$$\mathcal{D}_1 = R_1(r)(\delta_1 \mathbf{r})(\delta_2 \mathbf{r}), \quad R_1(r) = (e^4/8mc^2)r^{-4} \quad (28''')$$

The \mathbf{M} are the orbital angular momentum operators $[\mathbf{r} \times \mathbf{p}]$. We have included here only those terms of the perturbation energy which have an influence on the fine structure and we have omitted therefore terms in $(\delta_1 \delta_2)$. The first three terms of (28) i.e. (28'), (28'') are of the second degree in the electronic charge e and the last is of the fourth degree. We have written this last term separately so as to be able to see the result with it and without it. Letting

$$C = A + B \quad (29)$$

we have

$$\begin{aligned} (A\delta_1 + B\delta_2)uS_1 &= C_z uS_1 + 2^{-1/2}(C_x + iC_y)uS_0 \\ (A\delta_1 + B\delta_2)uS_0 &= 2^{-1/2}(C_x - iC_y)uS_1 + 2^{-1/2}(C_x + iC_y)uS_{-1} \\ (A\delta_1 + B\delta_2)uS_{-1} &= 2^{-1/2}(C_x - iC_y)uS_0 - C_z uS_{-1} \end{aligned} \quad (30)$$

On the right side of these formulas all terms in the antisymmetric combinations $2^{-1/2}(S_\alpha^1 S_\beta^2 - S_\alpha^2 S_\beta^1)$ have been omitted since they do not belong to the triplet state. We are justified in doing this in the present calculation because the formulas (30) are to be used in the calculation of matrix elements for the secular equation and only matrix elements between eigenfunctions belonging to the unperturbed 3P state are of interest to us. Similarly we find¹⁷

$$\begin{aligned} (\delta_1 \mathbf{r})(\delta_2 \mathbf{r})S_1 &= z^2 S_1 + (2)^{1/2} z(x + iy)S_0 + (x + iy)^2 S_{-1} \\ (\delta_1 \mathbf{r})(\delta_2 \mathbf{r})S_0 &= (2)^{1/2} z(x - iy)S_1 + (x^2 + y^2 - z^2)S_0 - (2)^{1/2} z(x + iy)S_{-1} \\ (\delta_1 \mathbf{r})(\delta_2 \mathbf{r})S_{-1} &= (x - iy)^2 S_1 - (2)^{1/2} z(x - iy)S_0 + z^2 S_{-1} \end{aligned} \quad (31)$$

Formulas (30), (31) give the effect of all the operations due to the spins. Other angular momentum operations are involved in the operator C itself.

¹⁵ See (1). The σ 's are here Pauli's matrices with unchanged signs i.e. with signs opposite to those used in the above reference.

¹⁷ A systematic way of obtaining the matrices involved in (30) and (31) is to observe that $A\delta_1 + B\delta_2$ with symmetrical A, B is equivalent to an angular momentum matrix so far as operations on symmetric spin functions are concerned. From this point of view (30) is obvious and is easily generalized to any number of electrons. For (31) we can use (30) if it is remembered that $(\delta_1 \mathbf{r} + \delta_2 \mathbf{r})^2 = 2r^2 + 2(\delta_1 \mathbf{r})(\delta_2 \mathbf{r})$.

We see that

$$C = \frac{he^2}{8\pi m^2 c^2} \{ Z(r_1^{-3} \mathbf{M}_1 + r_2^{-3} \mathbf{M}_2) - 3^{-3} [(\mathbf{r}_1 - \mathbf{r}_2) \times (\mathbf{p}_1 - \mathbf{p}_2)] \}. \quad (30')$$

Applying C to the eigenfunctions u_1, u_0, u_{-1} it is found that

$$\begin{aligned} C_z(u_1, u_0, u_{-1}) &= C(u_1, u_0, u_{-1}) \\ (C_x + iC_y)(u_1, u_0, u_{-1}) &= C(0, -(2)^{1/2}u_1, (2)^{1/2}u_0) \\ (C_x - iC_y)(u_1, u_0, u_{-1}) &= C(-(2)^{1/2}u_0, (2)^{1/2}u_{-1}, 0) \end{aligned} \quad (32)$$

where

$$\begin{aligned} C = \left(\frac{eh}{4\pi mc} \right)^2 \left\{ Z \int \left[\frac{F^2}{r_1^3} + \frac{\tilde{F}^2}{r_2^3} - \left(\frac{1}{r_1^3} + \frac{1}{r_2^3} \right) F\tilde{F} \cos \theta + \frac{1}{2} \left(\frac{1}{r_1^3} \right. \right. \right. \\ \left. \left. - \frac{1}{r_1^3} \right) \left(\tilde{F} \frac{\partial F}{\partial \theta} - F \frac{\partial \tilde{F}}{\partial \theta} \right) \sin \theta \right] dV - 3 \int \frac{1}{r^3} \left[F^2 + \tilde{F}^2 - 2F\tilde{F} \cos \theta \right. \\ \left. + \frac{r_1}{r_2} \tilde{F}(F - \tilde{F} \cos \theta) + \frac{r_2}{r_1} F(\tilde{F} - F \cos \theta) + \frac{1}{2} \sin^2 \theta \left\{ r_2 \left(\tilde{F} \frac{\partial F}{\partial r_1} \right. \right. \right. \quad (33) \\ \left. \left. - F \frac{\partial \tilde{F}}{\partial r_1} \right) - r_1 \left(\tilde{F} \frac{\partial F}{\partial r_2} - F \frac{\partial \tilde{F}}{\partial r_2} \right) + \left(\frac{r_2}{r_1} - \frac{r_1}{r_2} \right) \left(\tilde{F} \frac{\partial F}{\partial \theta} - F \frac{\partial \tilde{F}}{\partial \theta} \right) \cot \theta \right. \\ \left. \left. - \left(\frac{r_2}{r_1} + \frac{r_1}{r_2} \right) F\tilde{F} \right\} \right] dV \right\}. \end{aligned}$$

It is also found that:

$$\begin{aligned} (2)^{1/2} z(x + iy) R(r)(u_1, u_0, u_{-1}) &= (0, Du_1, Du_0) \\ (2)^{1/2} z(x - iy) R(r)(u_1, u_0, u_{-1}) &= (Du_0, Du_{-1}, 0) \\ (x + iy)^2 R(r)(u_1, u_0, u_{-1}) &= (2Du_{-1}, 0, 0) \\ (x - iy)^2 R(r)(u_1, u_0, u_{-1}) &= (0, 0, 2Du_1) \\ (r^2 - 3z^2) R(r)(u_1, u_0, u_{-1}) &= (Du_1, -2Du_0, Du_{-1}) \\ z^2 R(r)(u_1, u_0, u_{-1}) &= (D'u_1, (D + D')u_0, D'u_{-1}) \end{aligned} \quad (34)$$

with

$$\begin{aligned} D &= \int \frac{1}{5} \{ 2(a\alpha + b\beta)^2 - (a\beta - \alpha b)^2 \} R(r) dV \\ D' &= \int \frac{1}{5} \{ (a\alpha + b\beta)^2 + 2(a\beta - \alpha b)^2 \} R(r) dV \end{aligned} \quad (35)$$

where

$$a = F - \tilde{F} \cos \theta, b = \tilde{F} \sin \theta, \alpha = r_1 - r_2 \cos \theta, \beta = r_2 \sin \theta. \quad (35')$$

In formulas (32), (34) we omit everywhere terms involving other functions than u_1, u_0, u_{-1} . The reason for this is the same as that for the omission of terms in $2^{-1/2} (S_\alpha^1 S_\beta^2 - S_\alpha^2 S_\beta^1)$ in (30), (31). These formulas (30), (31), (32), (34) can be used to form the secular determinant for the whole problem.

It is known that the matrix elements of ΔH between any two eigenfunctions belonging to different rows in (27) must vanish and that, therefore, the secular determinant can be broken up into five independent subdeterminants. With the aid of the results just described it is found that the subdeterminant $m=0$ is

$$\begin{vmatrix} -C - \lambda', & C + D, & 2D \\ C + D & -D - \lambda' & -C - D \\ 2D, & -C - D, & -C - \lambda' \end{vmatrix} = 0, \quad \lambda' = \lambda - D' \quad (36)$$

having roots $\lambda' = (-2C - 3D, 2D - C, C)$. The other subdeterminants are similarly found and give some of the same roots the first occurring on the whole 1, the second 3, and the third 5 times. The result is that the energy is to within a common additive constant

$$E = E_0 + [-3(C + D), 2(D - C), 0] \quad (1)^{18}$$

for $j=0, 1, 2$.

§IV COMPUTATION OF C AND D ¹⁹

Formula (6) is substituted into (33) and the integrations are performed. It is found that

$$\begin{aligned} \int (F^2 r_1^{-3} + \tilde{F}^2 r_2^{-3} - F\tilde{F} r_1^{-3} \cos \theta - F\tilde{F} r_2^{-3} \cos \theta) dV \\ = 8a^{-2}b^{-3}(1 + c^2/3) + 16c(a/2 + b/2)^{-5}. \end{aligned} \quad (37)$$

In the remainder of the calculation terms in c^2 are dropped, this being justified by the small numerical value of c .

$$\begin{aligned} \int r^{-3} \left\{ 2F^2 - 2F\tilde{F} \cos \theta + 2(r_1/r_2)(F\tilde{F} - \tilde{F}^2 \cos \theta) + (1/2) \sin^2 \theta \left[2r_2 \left(\tilde{F} \frac{\partial F}{\partial r_1} - F \frac{\partial \tilde{F}}{\partial r_1} \right) - 2(r_2/r_1)F\tilde{F} \right] \right\} dV \\ = 8 \left[\frac{1}{a^2 b (a+b)^2} + \frac{2b-a}{ab(a+b)^4} + \frac{20b}{(a+b)^6} \right] \\ + 16c \left[\frac{2b-a}{ab(a+b)^4} + \frac{2}{(a+b)^6} + 4.168 \frac{b-a}{(a+b)^6} \right]. \end{aligned} \quad (38)$$

Here $4.168 = (16/5) (120 \log 2 - 81.875)$. Substituting these expressions into (33), remembering the normalization condition (5) and (9), then substituting

¹⁸ The same result can be checked by using the theorem emphasized by Slater: the sum of the roots of a secular determinant is equal to the sum of the diagonal elements. The first row in (27) gives the last root ($j=2$), the second gives the sum of the last two, the third the sum of the three roots.

¹⁹ The writer is very grateful to Dr. F. W. Doermann for checking some of these formulas.

the dimensionless constants x, y by means of (19) and noting that $G^3\mu^2 = 4Z^3R_H\alpha^2$ we have

$$\left(1 - 128 \frac{x^5 y^3}{(x+y)^8} c\right) C = R_H Z^3 \alpha^2 x^3 \left\{ \frac{Z}{6} \left[1 - \frac{64 x^2 y^3}{(x+y)^5} c \right] - \frac{1}{2} \left[\frac{y^2}{(x+y)^2} + \frac{xy^2(2y-x)}{(x+y)^4} + 20 \frac{x^2 y^4}{(x+y)^6} \right] - c \left[\frac{xy^2(2y-x)}{(x+y)^4} + \frac{2x^2 y^3}{(x+y)^5} + 4.168 \frac{y-x}{(x+y)^6} \right] \right\}.$$

The first term involving Z is due to the action of the electric field of the nucleus and the remaining part of C is due to the interaction of the two electrons. It is seen that the two parts of C have opposite signs. For large Z the first part predominates and gives the usual effect for high atomic numbers. For small Z the second part may be numerically the larger one and C may be negative.

The part of D arising from \mathcal{D}_0 , given by (28''), is similarly found to be D_0 given by

$$\begin{aligned} \left(1 - 128 \frac{x^5 y^3}{(x+y)^8} c\right) D_0 = & - (R_H Z^3 \alpha^2 x^3 / 5) \left\{ \frac{y^2}{(x+y)^2} + \frac{xy^2(2y-x)}{(x+y)^4} \right. \\ & \left. + 2c \left[\frac{xy^2(2y-x)}{(x+y)^4} + \frac{xy^2}{(x+y)^3} - \frac{4x^2 y^3}{(x+y)^5} \right] \right\}. \end{aligned} \quad (40)$$

The part of D arising from \mathcal{D}_1 , given by (28'''), is, neglecting c altogether

$$\begin{aligned} D_1 = (R_H Z^2 \alpha^2 x^2 / 120) & \left[3 + \frac{256 x^3 y^3}{(x+y)^6} + 48 \frac{x^4 y^4 (x^2 + 3y^2)}{(x^2 - y^2)^5} \log \frac{x}{y} \right. \\ & \left. + 2x^2 y^2 \frac{x^4 - 11y^4 - 38x^2 y^2}{(x^2 - y^2)^4} + \frac{2x^2 y^2}{(x^2 - y^2)^2} + \frac{y^2 + 3x^2}{y^2 - x^2} \right] \end{aligned} \quad (41)$$

Substituting the numerical values of x, y, c of §2 the values of C, D_0, D_1 listed in §1 are obtained.

THE SINGLET SYSTEM OF THE OXYGEN ARC SPECTRUM
AND THE ORIGIN OF THE GREEN AURORAL
LINE

BY RUDOLF FRERICHS*

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received June 2, 1930)

ABSTRACT

The oxygen arc spectrum has been investigated under varied conditions in the extreme ultraviolet. A number of observed lines have been arranged in the singlet system of terms. The values of the low terms 1D_2 and 1S_0 have been fixed

AS J. C. McLennan has shown,¹ the green auroral line $\lambda=5577.35\text{\AA}$ gives the Zeeman pattern of a singlet line and is therefore probably the forbidden combination between the low metastable terms 1D_2 and 1S_0 of the oxygen atom. Although many attempts have been made to locate these terms, either by extrapolating the values of the corresponding terms of similar spectra or by connecting the structure of the oxygen band spectra with the dissociation energy, the exact position of these terms could not be fixed. The direct method of locating the terms by spectroscopic analysis was not used in former investigations.

The following paper gives an attempt to classify all the stronger ultraviolet singlet lines of the oxygen atom. The classification of singlet lines is usually more difficult than the classification of lines of higher multiplicity. Therefore, we have investigated the oxygen arc spectrum under different controlled conditions in order to obtain information regarding the excitation potential of the different lines. The results so obtained are given in part 2 after a short description of the experimental arrangement in part 1. Part 3 discusses the series analysis of the new lines.

APPARATUS AND PROCEDURE

Two different gratings were used. The first one, ruled by Anderson, (Focus = 1 m, area 5×8 cm, dispersion: first order 17A per mm) gives very good definition (see Table I) but unfortunately scatters the light so much that it could not be used for weak lines. The other one, ruled at the National Physical Laboratory, (Focus = 1 m, area 3.5×5 cm, dispersion 18A per mm) shows very bright and sharp lines down to 520A, the smallest wave-length here investigated, although it was not made with light rulings for the ultraviolet.

The spectrograph built for this investigation was very simply constructed. It consists of a brass tube which carries at one end the grating, at the other

end, the slit and holder for uncurved plates 1"×4" in size. The cover plates on the two ends of the spectrograph are sealed with rubber gaskets inserted in small circular grooves and are held in place with screws. These gaskets proved to be very satisfactory. Over one hundred exposures were made without the slightest trouble from leaks in the spectrograph.

Much care was taken in the arrangement of the pumping system and the light source. Small traces of oxygen in the spectrograph cause absorption of the light as well as serious fogging of the plates. In order to obtain as great a pressure difference as possible between the discharge tube and spectrograph we used two slits in series. The outer slit, narrow (0.01 mm) and short (2 mm) was sealed to the spectrograph so that the only communication between the discharge tube and the spectrograph was through this narrow aperture. A small distance behind this slit, there was a second slightly larger slit arranged at the end of a conical tube. One two-stage pump evacuated the space between these two slits, a second one the spectrograph directly, all connections were made with short and large tubes.

In order to make experiments on the excitation energy of the singlet lines the spectrograph was equipped with arrangements to work either with pure oxygen or with circulating mixtures of oxygen and rare gases. The oxygen was generated electrolytically. Small traces of hydrogen could be oxidized by a glowing platinum wire. The gas was dried with phosphorus pentoxide and then stored under low pressure in a bulb with a side tube immersed in liquid air. The flow of the oxygen in the discharge tube was regulated by a narrow capillary. A variable valve was not used but the amount of gas flowing in the tube was kept exactly constant by regulating the pressure in the storage bulb. The discharge tube was evacuated through two single stage pumps in series. For the experiments with pure oxygen, these four pumps were backed by an oil-pump. For the experiments with helium-oxygen and with neon-oxygen, the four pumps exhausted the gas from the spectrograph and discharge tube into a large bulb with a back pressure of about five millimeters. From this bulb the gas flowed back to the discharge tube through a heated quartz tube with copper oxide and a large charcoal trap in liquid air. The charcoal kept all impurities back and after a short time of circulation, the spectrum of the discharge tube was free from impurities. The charcoal also adsorbed the oxygen of the mixture and we had therefore to add continuously a small amount of oxygen to the rare gas after it had passed the charcoal. Argon is strongly adsorbed by charcoal. Therefore, the argon-oxygen mixture was circulated over calcium heated to about 300 degrees C in an iron tube and through a trap in liquid air, and new oxygen was added to replace that absorbed in the calcium tube.

The experiments were made with the positive column as well as with the hollow cathode in pure oxygen and in different mixtures. The discharge tube that was finally adopted had a diameter of about 15 mm and a length of 250 mm. Large electrodes of heavy aluminum allowed the use of currents of between 350 and 750 milliamperes. Direct current at 1300 volts was supplied by two small generators of 650 volts each, connected in series. Suit-

able ballast-resistance was used. The hollow cathode consisted either of a small aluminum tube 10 mm in diameter and 40 mm in length or of a hole of similar size in a solid piece of aluminum, which was cooled by water flowing through a copper-tubing surrounding the aluminum. The hollow cathodes carried currents of between 150 and 500 milliamperes.

In front of the slit, there was a small shutter which was closed before an exposure, while the discharge tubes were run at the heaviest possible currents until the last traces of visible bands and of the hydrogen lines disappeared. Table I gives the observed lines which we can attribute with safety to the spectrum of the oxygen atom. The exposures were made with times between 15 minutes and three hours. Most of the lines were measured in the second order against some lines of impurities: O II, NI, N II, CI, CII which have

been determined by Bowen and Ingram² with great accuracy, and which occurred weakly in our discharge. A few weaker lines have been measured only in the first order against O II, O I, Ne, He. As the intensities vary considerably with the source, intensity values are only relative and only given for lines which belong to one group.

THE EXCITATION POTENTIAL OF THE ULTRAVIOLET OXYGEN LINES

In order to obtain a classification of the oxygen lines, we investigated the spectrum under varied conditions. A few pictures were taken with the above mentioned positive column in the mixtures: He-O₂, Ne-O₂ and A-O₂. The pressure of the rare gas was not measured but was always adjusted to give the minimum potential drop across the tube. The amount of oxygen added continuously was so small that the stronger lines were just visible in a spectroscope of considerable dispersion. The excitation phenomena of mixtures of rare gases with other gases and vapors have been studied much and discussed in the last years. Although there are some discrepancies between the results of different observers, we can state with safety that the maximum amount of energy available in such a discharge is given by the ionization potential of the rare gas, when the amount of the other component of the mixture is small. These investigations differ only as to whether this amount is transferred to neutral atoms, to metastable atoms or to ions of the second component. In the case of discharges through mixtures of rare gases and molecular gases, the process is complicated by dissociation. By looking over various experiments carried on in this field, one gains the impression that the assumptions of different kinds of collisions are made *ad hoc* in order to obtain agreement with the observed facts.³ Therefore, because the prediction of the excitation limit of unclassified lines seemed to be rather uncertain, we have made no special assumptions as to the processes involved, but we have empirically calibrated our results by the well-known excitation energy of the already classified oxygen lines. Table II gives the results so obtained. The fifth column contains the excitation energy of the upper level of each line in frequency units, the second, third and fourth column the intensities in A-O₂, Ne-O₂ and He-O₂. Fig. 1 illustrates these results. The exposures are so chosen, that the resonance lines appear on all spectrograms with nearly the same intensity. In argon, only those lines whose upper level is not higher than about 100,000 frequency units above the ³P₂ level are excited with considerable intensity (>1). This photograph shows clearly that 1152 is the lowest excited line of the singlet system because the other lines are either very weak or absent in argon-oxygen. Neon has a very remarkable effect on the intensities. Table II shows that in neon, the line 935.15, whose upper level is about 122800 above the ³P term, is strongly

² I. S. Bowen and S. B. Ingram, Phys. Rev. **28**, 444 (1926).

³ For a discussion of the various kinds of collision which are necessary to explain the observed facts in mixtures of rare gases and molecular gases, see O. S. Duffendack and H. L. Smith, Phys. Rev. **34**, 68 (1929) and O. S. Duffendack and R. A. Wolfe, Phys. Rev. **34**, 409 (1929).

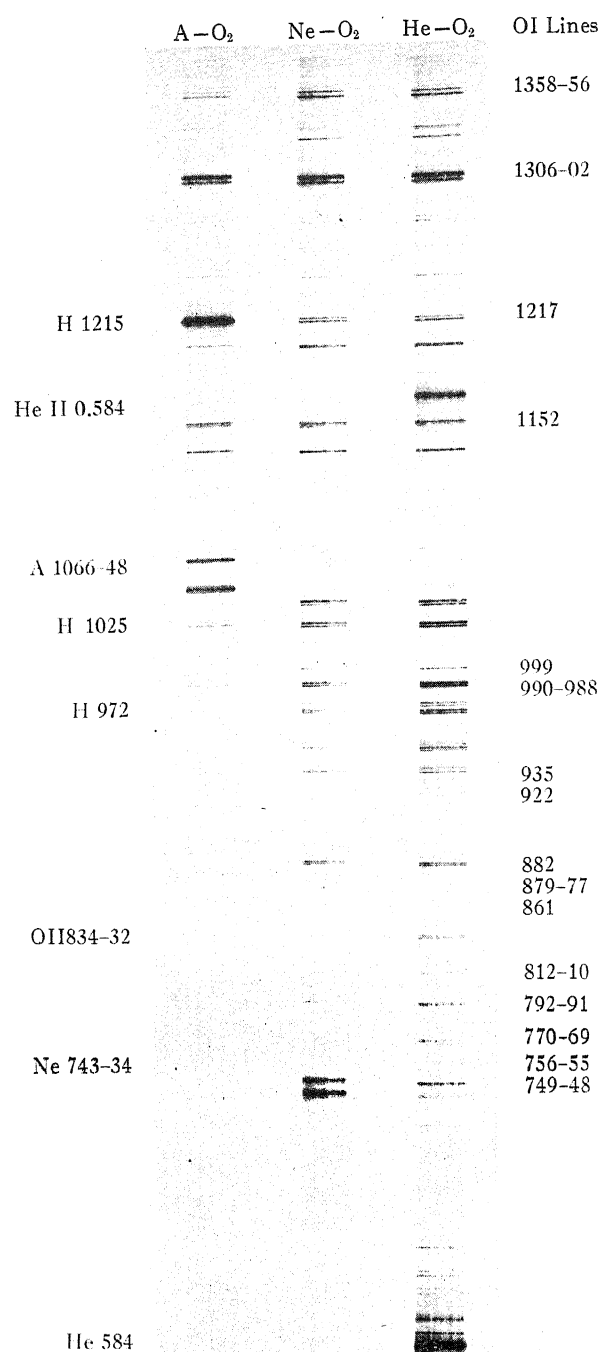

Fig. 1. The ultraviolet OI spectrum in A-O₂, Ne-O₂ and He-O₂.

excited. This phenomenon of increased intensities of certain lines in such discharges often has been mentioned.⁴ It occurs always when either the ionization energy or the energy of the metastable state of the rare gas is approximately equal to the excitation energy of the line of the other component.

These lines are strongly excited in helium-oxygen but on the other hand, some more lines can be observed in helium which are either weak or absent in neon.

A few words may be said about the excitation of the oxygen arc spectrum in other sources. The positive column in pure oxygen also shows these lines but the intensity at the same amount of current passing through the tube is much smaller than in the mixtures of rare gases and oxygen. In pure oxygen the lines show the usual decrease in intensity with increasing excitation.

The highest amount of excitation with direct current is obtained in the hollow cathode in pure oxygen. In the hollow cathode, all the lines of of O II which have been classified by Bowen⁵ are strongly developed. We also observed the hollow cathode discharge in mixtures of He-O and Ne-O. The spectra so obtained show generally the same lines as the spectra taken with the positive column. The intensity is much smaller and the spectra cannot be so brilliantly excited as in the positive column with great current density.

$3s^1D_2$. Our experiments on the excitation of the different lines (Table II) show that this last line has a lower excitation potential than the other two, in accordance with this classification.

We have now succeeded in finding five members of the series: $2p^1D_2 - ({}^2D)ns^1D_2$. According to Table III, their frequency differences are always between the corresponding frequency differences of the $({}^4S)ns^5S_2$ and $({}^4S)ns^3S$ terms. This demonstrates again how accurately the new terms can be obtained by the above mentioned displacement of the Runge-Paschen terms. We have used these five members to calculate the limit of this series in order to locate the important $2p^1D_2$ term.

These $({}^2D)ns^1D_2$ terms have for their limit the low metastable term 2D of the O II spectrum. This term has been located by Bowen⁸ not only by ultraviolet combinations with higher terms but also more accurately by the forbidden combinations with the lowest term: 4S , i.e. the nebular lines 3729.91 and 3727.12, according to his well-known theory. As Hund has shown in Table 34 of his book, the series of the 1D_2 terms have in this case the ${}^2D_{3/2}$ component of the doublet term for a limit. This term is inverted and according to Shenstone,⁹ there are some deviations known from Hund's rule in the case of inverted terms. But Shenstone states in his second paper that, in the case of the addition of an s -electron, this rule holds even for inverted terms. The possible error caused by a failure of Hund's rule would be in this case, ${}^2D_{3/2} - {}^2D_{1/2} = 20$ frequency units.

TABLE III. The OI series $2p^1D_2 - ({}^2D)ms^1D_2$.

$({}^4S)ns^3S_1$:	33043.3	13612.5	7425.6	4672.8	3210.2	2340.9

$2p^1D_2 - ({}^2D)ns^1D_2$ {	λ	1152.06	935.15	882.88	861.63	850.74
	ν	86801	106935	113266	116059	117545
	$\Delta\nu$	20134	6331	2793	1486	
$\Delta({}^4S)ns^5S_2$:	21710.5	6637.7	2902.9	1526.0	900.3	
$({}^4S)ns^5S_2$:	36069.0	14358.5	7720.8	4817.9	3291.9	2391.6

We have tried to get higher series members under conditions where the first four members are strong, but the fifth is always weak and it was not possible to obtain higher members. This is not astonishing when one considers how highly unstable such an atom is in a state 24,000 frequency units above the ordinary ionization limit. However, we can estimate the accuracy of this calculation in the following way. The value for the terms $({}^4S)ns^3S_1$ and $({}^4S)3s^5S_2$ which is obtained by applying the Rydberg formula to four series members departs only about 6 frequency units from the value which can be obtained by using eight or nine series members. Adding the fifth member reduces this error to 3 frequency units. We believe, therefore, that the error in the limit of our singlet series caused by this method of calculation is not greater than about 3 frequency units, because these terms are located

⁸ I. S. Bowen, reference 5.

⁹ A. G. Shenstone, Nature **121**, 619 (1928); Nature **122**, 727 (1928).

exactly between the corresponding $(^4S)ns^3S_1$ and $(^4S)ns^5S_2$ terms. The only important source of error will therefore be the comparatively small accuracy in the frequencies at these short wave-lengths.

By this determination the energy values of the terms involved in the emission of the green auroral line are fixed. As we have mentioned above, the classification of this line has been suggested some time ago by McLennan. In the meantime, many attempts have been made to locate these terms. Some predictions of their position have been made by assuming that the relative position of the metastable low terms 1S_0 and 1D_2 is the same for similar spectra. Sommer as well as Kaplan¹⁰ calculate from the known position of the 1S_0 , 1D_2 and 3P term in O III the distance $^1D_2 - ^3P$ to be about 15500 frequency units. This is apparently in very good agreement with the observed position although Sommer as well as Kaplan could not give any theoretical reason for their assumption. In a letter to Nature,¹¹ J. C. McLennan and M. F. Crawford find that the ratio $^1D_2 - ^3P : ^1S_0 - ^1D_2$ is constant and equal to 0.585 for selenium and tellurium and they assume that this ratio is the same for sulphur and oxygen. Thus, by using the value $^1S_0 - ^1D_2 = 17925$, they find $^1D_2 - ^3P = 10490$. But by comparing the relative positions of such terms in other columns of the periodic table: i.e., C I, Si I, Ge I, Sn I, Pb I or O II, S II, one finds that the ratio between the low terms in all the cases where they are known, is never constant and, therefore, it seems to be without any justification to predict unknown terms in this way.

Another method of prediction of the approximate position of this 1D_2 term is based on the calculation of the dissociation energy by means of the convergence point of the oxygen bands. Herzberg¹² has shown that the convergence limit of the Birge-Spencer bands does not correspond to a dissociation into two oxygen atoms in the normal 3P_2 state, but to a dissociation into one atom in the 3P_2 state and another atom in the 1D_2 state. By comparison of the so calculated dissociation energy $O_2 \rightarrow O_{1D_2} + O_{3P_2}$ with the chemically measured value $O_2 \rightarrow O_{3P_2} + O_{3P_2}$, one obtains the value $O_{1D_2} - O_{3P_2}$. In this way Mecke¹³ obtains $^1D_2 - ^3P_2 = 1.4$ volts, Henri¹⁴ $^1D_2 - ^1P_2 = 1.7$ volts the latter value being in better agreement with the observed value: 1.95 volts.

A few words may be said about some other combinations which can be calculated from the known position of the singlet terms. We have not found any intercombination between singlet and triplet terms. The theory of the intensity of intercombinations between singlet and triplet terms has been developed by Houston¹⁵ for atoms with two outer electrons. This theory predicts, in good agreement with the observations, that intercombinations are strong only when the interval between singlet and triplet terms is small compared with the intervals between the different components of the triplet

term. Although this theory cannot be applied to the more complicated case of the oxygen atom, the very small intervals of the oxygen terms may be responsible for the missing intercombination lines. It is in agreement with Houston's theory that, in the case of selenium and tellurium, where the intervals are much larger, such intercombinations have been found by McLennan.

The green auroral line is according to its classification, the exact analogue of the nebular line 4363.21A. We should therefore expect to find also the other combinations ${}^3P_2-{}^1D_2$ and ${}^3P_1-{}^1D_2$ which correspond to the nebular lines 5006.84 and 4958.91A. According to Table IV, these lines are located at 6299 and 6363A with an error of approximately $\pm 5A$. These lines are neither found in the laboratory nor in the spectrum of the aurora or of the night sky.

Among the new triplet terms (Table IV), the term: $2s2p^5 {}^3P$ is especially interesting. By application of the irregular doublet law to the oxygen-like isoelectronic spectra, Mack and Sawyer¹⁶ have predicted its position as about 15000 frequency units above the ordinary ionization limit, the 4S term of the ion, in good agreement with the observed value. Under the unclassified lines in the near ultraviolet and in the visible, there are some triplets which give the intervals 58.9 and 32 frequency units. Table V shows that these triplets are combinations of this $2s2p^5 {}^3P$ term with the terms: $({}^4S)2s^2 2p^3 n p^3 P$. The combination $({}^4S)2s^2 2p^3 5p^3 P - 2s2p^5 {}^3P$ is not known, perhaps due to the small sensitivity of the photographic plates in this region. The term: $2s2p^5 {}^3P$ combines with a 3P term at 3926 and the application of the Rydberg formula shows that this term is the hitherto unknown term $({}^4S)2s^2 2p^3 6p^3 P$.

We are indebted to the Rockefeller Foundation for the grant of a fellowship, to Professor R. A. Millikan for extending the facilities of the Norman Bridge Laboratory and to Professor I. S. Bowen for helpful discussions and suggestions.

Note added with proof: Prof. Paschen writes me that he has recently observed the two lines ${}^3P_2-{}^1D_2$ and ${}^3P_1-{}^1D_2$ at 6300.06 and 6363.86A respectively in a discharge through pure oxygen. This proves that the above given calculation of the singlet terms is accurate within 0.5 frequency units. S. Goudsmit, Phys. Rev. **35**, 1325, (1930) finds by theoretical calculations the above mentioned value of McLennan in disagreement with our measurements. V. Kondratjew, Zeits. f. Phys. Chem. **B**, **7**, 70, (1930) obtains from the oxygen bandspectra the value 1.91 volts for the difference ${}^3P_2-{}^1D_2$ in very good agreement with the observed value 1.95 volts.

BAND SPECTRA INTENSITIES FOR SYMMETRICAL
DIATOMIC MOLECULESBY ELMER HUTCHISSON
BERLIN, GERMANY

(Received June 20, 1930)

ABSTRACT

The intensity of a spectral line may be calculated in the new quantum mechanics by evaluating the integral of the product of the electric moment and the wave functions of the initial and of the final states. The complete wave function may be written approximately as a product of a nuclear wave function and an electronic wave function. Furthermore, the electric moment can be approximately written as the sum of a function of the nuclear coordinates only and a function of the electronic coordinates only. For symmetrical diatomic molecules the term in the electric moment which is a function of the nuclear coordinates only is zero so that the intensity integral reduces to a double integral which may be written as a product of an electronic integral and a nuclear integral. The electronic integral is constant for all the lines corresponding to the same electronic transition and the integrand of the nuclear integral consists only of the product of the radial wave functions for the initial and the final states. The integration of the nuclear integral is carried out using harmonic oscillator wave functions whose origins are shifted due to the change of the nuclear separation during the electronic transition.

A comparison is made between the intensities calculated in the above manner and those obtained by experiment. In the case of Na_2 good quantitative agreement is obtained between the experimental and the calculated results. Accurate values of the moments of inertia in the initial and final states are not known for K_2 but it is possible to show that if a value of the change in the nuclear separations during the transition is assumed, agreement is possible for all of the lines corresponding to low quantum numbers. Good qualitative agreement is obtained for I_2 . Calculations are made for the absorption spectra and the $3'B-2'S$ emission band system of H_2 but the agreement in these cases is not as good as for Na_2 and K_2 .

I. INTRODUCTION

ON THE basis of the old quantum theory Condon¹ was able to show that in connection with a given electronic transition in a diatomic molecule certain transitions were more probable than others. His calculations were based upon Franck's² assumption that during an electronic transition nuclei which are originally in a non-vibrating state remain momentarily fixed because of their large masses compared with those of the electrons. Since the equilibrium distance between the nuclei is altered due to the motion of the electrons, the nuclei acquire a potential energy with respect to the new equilibrium points and begin to vibrate. The amplitude of the vibration acquired after the transition is approximately equal to the change in the equilibrium

¹ E. Condon, *Phys. Rev.* **28**, 1182 (1926).² J. Franck, *Trans. Faraday Society* (1925).

separations, therefore it is possible for the most probable nuclear transition to be calculated.

If the nuclei are vibrating in the initial state then almost any amplitude in the end state is possible. A calculation similar to that mentioned above can be employed except that instead of focusing our attention on the equilibrium position in the initial state, we focus our attention on the positions in which the nuclei spend most of the time. These positions will naturally be the turning points of the vibratory motion. With potential energy diagrams to determine the turning points of the vibration Condon was able to show that the positions of maximum intensities in the well-known double entry tables lie along a parabolic path and agree fairly well with experiment. As Condon's theory is essentially only one of transition probabilities the distribution in the initial state is not included.³

In a second paper Condon⁴ showed that the ideas expressed above on the basis of the old quantum theory could be carried over into the new quantum mechanics. In the new quantum mechanics the intensity of a spectral line may be calculated by evaluating the integral of the product of the electric moment and the wave functions of the initial and final states where the integration is carried out over all of the coordinates of the electrons and the nuclei. Thus a measure of the intensity is given by the expression (following Condon):

$$I = \int \int M(x, r) \psi_{e'n'}(x, r) \psi_{e''n''}(x, r) dx dr,$$

where M is the instantaneous electric moment, $\psi_{e'n'}$ and $\psi_{e''n''}$ are the wave functions of the initial and final states, x and r are total coordinates of the electron and of the nuclei respectively and e and n are electronic and vibrational quantum numbers. According to the work of Born and Oppenheimer⁵ the complete wave function ψ_{en} can be approximately expressed as a product of an electronic wave function $\Phi_e(x)$ and an oscillatory wave function $\Psi_{en}(r)$. The latter function corresponds to the motion of the nuclei moving under an effective force arising from the moving electrons and the repulsion of the nuclei. We may write our integral:

$$I = \int \int M(x, r) \Phi_{e'}(x) \Psi_{e'n'}(r) \Phi_{e''}(x) \Psi_{e''n''}(r) dx dr.$$

The electric moment is defined as the vector sum of the coordinates of the electrons times their charge and the coordinates of the nuclei times their charge. This may be approximately expressed in the following way:

$$M(x, r) = A(x) + B(r)$$

because during the transition of the electrons the nuclei remain practically fixed and the first term (representing the vector sum of the electronic charges

³ Cf. G. Herzberg, *Zeits. f. Physik* **49**, 761 (1928).

⁴ E. Condon, *Phys. Rev.* **32**, 858 (1928).

⁵ M. Born and Oppenheimer, *Ann. d. Physik* **84**, 457 (1927).

times x) will be a constant over the integration of the electron coordinates. The second term (representing the vector sum of the nuclear charge times r) will be a function of only the nuclear coordinates because the heavy nuclei cannot respond immediately to the changes in the electronic arrangement. We have therefore:

$$I = \int A(x) \Phi_{e'}(x) \Phi_{e''}(x) dx \int \Psi_{e'n'}(r) \Psi_{e''n''}(r) dr + \int \Phi_{e'}(x) \Phi_{e''}(x) dx \int B(r) \Psi_{e'n'}(r) \Psi_{e''n''}(r) dr.$$

The integrals involving the electron coordinates will be constant for a given electronic transition so that

$$I = C_1 \int \Psi_{e'n'}(r) \Psi_{e''n''}(r) dr + C_2 \int B(r) \Psi_{e'n'}(r) \Psi_{e''n''}(r) dr.$$

This integral cannot be evaluated in general because we do not know the ratio of the constants ($B(r)$ is probably a linear function). However if we restrict ourselves to symmetrical diatomic molecules the nuclear electric moment will always be zero so that the last term drops out and we have only

$$I = C_1 \int \Psi_{e'n'}(r) \Psi_{e''n''}(r) dr. \quad (1)$$

It is the purpose of this paper to evaluate this integral and to compare the results with experiment in several cases.

II. INTENSITIES FOR HARMONIC OSCILLATIONS

The approximate wave equation for the nuclear motions of the diatomic molecule may be written

$$\nabla^2 \Psi + \frac{8\pi^2\mu}{h^2} \left[W - \frac{Z^2 e^2}{r} + V_e(r) \right] \Psi = 0 \quad (2)$$

where Ze is the charge on one of the nuclei, μ is the equivalent mass ($= M_1 M_2 / M_1 + M_2$), r is the separation of the nuclei and $V_e(r)$ is the mean potential energy due to the electrons. The wave function may be separated into three functions in the usual manner by setting $\Psi = N\Phi(\phi) \cdot \Theta(\theta) \cdot R(r)/r$ where N is a normalizing factor. The equations in ϕ and θ will not have any effect⁶ on the calculated intensities of the spectral lines and we may therefore pass immediately to the equation in r

$$\frac{d^2 R}{dr^2} - \frac{m(m+1)}{r^2} R + \frac{8\pi^2\mu}{h^2} \left[W - \frac{Z^2 e^2}{r} + V_e(r) \right] R = 0 \quad (3)$$

⁶ A. Sommerfeld, *Ergänzungsband*, p. 69.

where m is the rotational quantum number. Making the substitution $\rho = r/r_0$ (r_0 = equilibrium separation of the nuclei) we obtain

$$R'' + \left[\frac{8\pi^2 J_0}{h^2} (W - f(\rho)) - \frac{m(m+1)}{\rho^2} \right] R = 0 \quad (4)$$

in which $J_0 = \mu r_0^2$ and $f(\rho)$ represents the effective potential energy.

In this paper we will restrict ourselves to linear oscillations and we may therefore put $f(\rho) = -D + [(2\pi\nu_0)^2 J_0/2] \xi^2$ where $\xi = \rho - 1$ and D is the dissociation energy and ν_0 is the frequency of vibration for very small amplitudes. Making use of this expression in Eq. (4) and expanding ρ in terms of ξ (or, one could set $m=0$) and finally making the substitution $\eta = 2\pi(\nu_0 J_0)^{1/2}/(h)^{1/2} \xi$, we obtain

$$R'' + \left[\frac{2}{h\nu_0} \left\{ W + D - m(m+1) \frac{h^2}{8\pi^2 J_0} \right\} - \eta^2 \right] R = 0 \quad (5)$$

which is the wave equation for the linear oscillator.⁷

The solution of this equation is well known and may be written

$$R_n = \frac{1}{N_n} e^{-\eta^2/2} H_n(\eta) \quad \text{and} \quad W + D - m(m+1) \frac{h^2}{8\pi^2 J_0} = \left[n + \frac{1}{2} \right] h\nu_0 \quad (6)$$

where n is the vibrational quantum number and $H_n(\eta)$ is a Hermitian polynomial.

We wish to evaluate the integral (1) which may now be written in terms of (ρ) and the radial wave function, in the following manner:

$$I = \text{const.} \int_0^\infty R_{e'n'}(\rho) R_{e''n''}(\rho) d\rho. \quad (7)$$

As far as the nuclei are concerned the effect of an electron transition is, that besides the change in the equilibrium positions of the nuclei there is also a change in the binding or potential energy such that the nuclei acquire a new vibration frequency after the transition. Therefore if we take $R_{e'n'} = (1/N_{n'}) e^{-\eta'^2/2} H_{n'}(\eta')$ as the nuclear part of the wave function for the upper state, we will have for the lower state $R_{e''n''} = (1/N_{n''}) \exp - [(\alpha\eta + \delta)^2/2] H_{n''}(\alpha\eta + \delta)$ where α and δ represent respectively measures of the change in frequency and the change in equilibrium position. From the definition of η we see that

$$\eta = [2\pi(\nu_0' J_0')^{1/2}/(h)^{1/2} r_0] r - 2\pi(\nu_0' J_0')^{1/2}/(h)^{1/2}$$

so that

$$\begin{aligned} \alpha\eta + \delta &= [(\alpha 2\pi(\nu_0' J_0')^{1/2}/(h)^{1/2} r_0')] [r + \delta r_0'/(h)^{1/2} 2\pi\alpha(\nu_0' J_0')^{1/2}] \\ &\quad - \alpha 2\pi(\nu_0' J_0')^{1/2}/(h)^{1/2} = [2\pi(\nu_0'' \mu)^{1/2}/(h)^{1/2}] r - 2\pi(\nu_0'' \mu)^{1/2} r_0''/(h)^{1/2}. \end{aligned}$$

Thus $\alpha = (\nu_0''/\nu_0')^{1/2}$ and

⁷ E. Fues, Ann. d. Physik **80**, 367 (1926).

$$\delta = (r_0' - r_0'') 2\pi(\nu_0''\mu)^{1/2}/(h)^{1/2} = 0.1221(r_0' - r_0'')(\nu_0''M)^{1/2}$$

where ν_0'' is expressed in cm^{-1} , M is the atomic weight ($\text{O} = 16$) of one of the atoms and $(r_0' - r_0'')$ is in Angstroms.

The integral (7) then becomes

$$I = \text{const} \int_{-\infty}^{+\infty} (N_{n'} N_{n''})^{-1} e^{-\eta^2/2} e^{-(\alpha\eta+\delta)^2/2} H_{n'}(\eta) H_{n''}(\alpha\eta + \delta) d\eta \quad (8)$$

where the limits are taken from $-\infty$ to $+\infty$ instead of from -1 to $+\infty$ since the addition of the region from -1 to $-\infty$ will not appreciably affect the value of the integral for small quantum numbers. The values of the normalizing factors are well known for the linear oscillator, being

$$N_{n'} = [2^{n'} n'! \pi^{1/2} h^{1/2} / 2\pi(\nu_0' \mu)^{1/2}]^{1/2} \quad N_{n''} = [2^{n''} n''! \pi^{1/2} h^{1/2} / 2\pi(\nu_0'' \mu)^{1/2}]^{1/2} \quad (9)$$

In order to carry through the integration of Eq. (8) the method used by Schrödinger⁸ in the Stark effect may be applied. The "erzeugende" function⁹ for the Hermitian polynomial is

$$\sum_{n'=0}^{n'=\infty} \frac{H_{n'}(\eta)}{n'!} s^{n'} = e^{-s^2+2s\eta}$$

and for the function of the lower state

$$\sum_{n''=0}^{n''=\infty} \frac{H_{n''}(\alpha\eta + \delta)}{n''!} t^{n''} = e^{-t^2+2t(\alpha\eta+\delta)}.$$

If these expressions are multiplied together and also multiplied by the exponentials in Eq. (8) we have after integration

$$\begin{aligned} \sum_{n'=0}^{n'=\infty} \sum_{n''=0}^{n''=\infty} \frac{s^{n'} t^{n''}}{n'! n''!} \int_{-\infty}^{+\infty} H_{n'}(\eta) H_{n''}(\alpha\eta + \delta) e^{-\eta^2/2} e^{-(\alpha\eta+\delta)^2/2} d\eta \\ = \int_{-\infty}^{+\infty} e^{-s^2+2s\eta-\eta^2/2} e^{-t^2+2t(\alpha\eta+\delta)-(\alpha\eta+\delta)^2/2} d\eta \\ = \left(\frac{2\pi}{\alpha^2 + 1} \right)^{1/2} e^{-\delta^2/2(\alpha^2+1)} e^{[(s^2-t^2)(1-\alpha^2)-2\alpha\delta s+2\delta t+4\alpha s t]/(1+\alpha^2)}. \end{aligned} \quad (10)$$

By expanding the last exponential factor in powers of s and t and then equating the like powers of s and t on both sides of the equation we obtain for the expression for the integral for each value of n' and n'' . Making use of Eqs. (9), Eq. (8) becomes

$$\begin{aligned} \int_{-\infty}^{+\infty} (N_{n'} N_{n''})^{-1} e^{-\eta^2/2} e^{-(\alpha\eta+\delta)^2/2} H_{n'}(\eta) H_{n''}(\alpha\eta + \delta) d\eta \\ = C_s \frac{(n'! n''!)^{1/2}}{2^{(n'+n'')/2}} \sum_{l=0}^{n' \text{ or } n''} \sum_{i=0}^{(n'-l)/2} \sum_{j=0}^{(n''-l)/2} a_{2l} b_{2i} c_{2j} d_{n'-2i-l} e_{n''-2j-l} \end{aligned} \quad (11)$$

$(n'n')$ by interchanging subscripts on "b" and "c" and on "d" and "e", i.e. $a_2b_2c_0d_1e_2$ becomes $a_2b_0c_2d_2e_1$. All coefficients with the subscript zero are equal to unity and are therefore omitted.

III. COMPARISON WITH EXPERIMENT

In the preceding section a formula is developed which allows the matrix elements of the electric moment to be calculated for vibration transitions in symmetrical diatomic molecules. The relative intensities of the bands in the electronic-vibration spectra of these molecules are calculated by squaring the integral (11) and multiplying by the fourth power of the frequency and by the

distribution factor of molecules in the initial state.⁹ It is somewhat difficult to know exactly what frequency to multiply by because the intensity obtained should apply to the sum of all the rotational transitions which have the same vibrational and electronic quantum numbers. If the rotational quantum number in Eq. (4) is set equal to zero then we should expect our calculated intensities to agree with those in the $Q(0)$ branch corresponding to the given electronic and vibrational transition. However, in any case, the changes in the frequencies associated with different vibrational transitions are very small since the change in vibrational energy is very small compared to the change in the electronic energy. Since the frequency factors do not appreciably affect the comparison of the calculated results with experiment, they have been omitted in the tables given below.

It is practically impossible at present to calculate accurately the expected intensity in emission spectra because the distribution factor for the initial state depends not only upon the temperature but also upon the method of excitation and upon whether or not the molecules have reached their initial excited levels by means of a transition from a higher level. It should be possible however, to calculate the relative intensities of those bands which originate from the same initial vibrational level and the emission diagrams should show agreement in the horizontal rows. In absorption spectra it is easily possible to calculate the expected absorption intensity for a given temperature because in this case the distribution factor is merely the appropriate Boltzmann factor. However, when we try to compare the calculated results with experiment we find that the exact temperature or pressure is seldom recorded in absorption spectrum intensity measurements. In the following calculated results no attempt has been made to include the temperature factor because of the uncertainty in the exact temperatures used in obtaining the experimental results. We have calculated the intensities for the first few vibrational levels only (because of the restriction to harmonic oscillations) so that in some cases the temperature distribution will not vary greatly from a uniform distribution and merely the squares of the integral (11) should be in approximate agreement with the experimental results, in other cases, only the agreement in the columns (for absorption) should be considered.

In making the theoretical intensity calculations the values of α and δ are first calculated. The value of α which is given by $(\nu_0''/\nu_0')^{1/2}$ is usually very well known since it comes from an analysis of the vibrational energy levels themselves. The value of α may therefore be determined to within three significant figures. The value of δ depends upon the values of the separations of the nuclei which in turn depend upon the values of the moments of inertia given by the analysis of the rotational spectrum. The values of the nuclear separations thus calculated are usually accurate only to within about 1 percent so that δ which depends upon the difference in the separations in the initial and final states ($\delta = 0.1221 (r_0' - r_0'') (\nu_0'' M)^{1/2}$) is, in general, susceptible to quite large errors. The next step in the calculations

⁹ Cf. A. Sommerfeld, *Ergänzungband*, p. 96.

is to evaluate the coefficients a, b, c, d , and e given after Eq. (11). The triple sum in Eq. (11) is then evaluated which in the highest state ($n'=4, n''=3$) considered, consists of 13 terms. In the diagrams given below the observed and calculated intensities are given in the usual double-entry form. In every case the observed intensities are placed on top and the corresponding calculated ones are given directly underneath them. Each element will be treated in a separate section.

a. Sodium.

The experimental and calculated data for the green absorption band of sodium (Na_2) are shown completely in Fig. 1. It may be seen that here the agreement is rather remarkable, perhaps much better than one would expect

$n' \backslash n''$	0	1	2	3	4

Fig. 1. Observed and calculated intensities in the green Na_2 absorption band. The observed values are placed on top.

with the available intensity measurements which are only estimates.¹⁰ The experimental intensities are taken from Fredrickson and Watson.¹¹ The values of the frequencies and of the nuclear separations are taken from Loomis and Wood¹² and give for α and δ the values 1.130 and 2.43 respectively. Fredrickson and Watson give the nonappearance of the bands (1-2), (2-1), (3-1), (2-2) and (1-3) as an especial characteristic of this system and the calculated intensities indicate very definitely the fact that these particular bands should be very faint. The calculated intensities in the positions (1-2) and (2-1) are quite sensitive to changes in the nuclear separations and indeed, when the writer first calculated these intensities, he used the value $r_0' - r_0'' = 0.40 \cdot 10^{-8}$ cm given by Fredrickson and Watson and found complete disagreement with experiment since the values in the positions (1-2) and (2-1) were approximately 12 on the same scale as used in Fig. 1. Later he found that Loomis

¹⁰ The Physical Review Referee has kindly pointed out that since at 1000°K the relative distribution in the initial states $n''=0,1,2,3,4$ is 1.00, 0.80, 0.64, 0.51, 0.41 respectively, the agreement in the top row of Fig. 1 can only be accidental and that the agreement in the columns only should be noticed.

¹¹ W. R. Fredrickson and W. W. Watson, Phys. Rev. **30**, 429 (1927).

¹² F. W. Loomis and R. W. Wood, Phys. Rev. **32**, 223 (1928).

and Wood had pointed out errors in Fredrickson and Watson's analysis and that they gave instead the value $r_0' - r_0'' = 0.33 \cdot 10^{-8}$ cm from which the values given were calculated.

b. Potassium.

Fredrickson and Watson¹¹ give an intensity diagram for the near red potassium absorption band which is very similar to the green band of sodium. However, as was the case with sodium, the nuclear separations which they give ($r_0' - r_0'' = 0.43 \cdot 10^{-8}$ cm) do not give calculated intensities which agree at all with experiment. It is interesting however, that because of the absence of the (1-2) and (2-1) bands and because of the likeness to Na_2 it is possible to estimate the change in the nuclear separation for K_2 . The value of δ which is obtained is almost the same as that for Na_2 and since $(\nu_0'' M)^{1/2}$ is practically identical in both cases the value of $r_0' - r_0''$ can be estimated to be close to the same value as for sodium ($0.33 \cdot 10^{-8}$ cm) although it may possibly be as low as $0.29 \cdot 10^{-8}$ cm. The agreement for only the first few terms when $0.33 \cdot 10^{-8}$ cm is used is shown in Fig. 2. The principle point in favor of the

$n' \backslash n''$	0	1	2
0	3 3.00	8 7.02	9 8.97
1	10 8.64	5 7.68	— 1.80
2	8 11.55	— 1.13	2 1.86

Fig. 2. Observed and calculated intensities in the near red K_2 absorption band. The observed values are placed on top.

argument for the change in separations chosen is that the *only* value, which gives a general agreement throughout all terms, is just the value which reduces the (2-1) and (1-2) terms to a very small value.

c. Iodine.

The iodine spectrum is characterized by the fact that intense bands correspond to changes of very large quantum numbers. Because of this fact it is obvious that we cannot expect to calculate the exact intensities by the integral (11) which is derived on the assumption of harmonic oscillations. We can however, draw important qualitative conclusions from this formula. If we restrict ourselves to the first column, that is, to all bands which result from a transition from the lowest initial vibrational state, we find that the most important term in the theoretical calculation is the d term which has the same index as the vibrational quantum number of the end state n' . The constants given by Mecke¹³ for iodine give $\alpha = 1.300$ and $\delta = 14.9$. Because of the large value of δ we find it is just the d coefficients which are extremely

¹³ Mecke, Handbuch der Physik XXI, p. 547.

large, in fact d_{14} is about 20,000 times d_0 . The values of the coefficients go up rather rapidly to a maximum at d_{14} and then slowly decrease. To calculate the intensities we must square these values of d and multiply by the square of the normalizing coefficient which tends to shift the maximum intensity in the direction of large quantum numbers. It requires therefore no stretch of the imagination to conclude that the first terms will be insignificant with respect to later ones and that observable terms will begin to appear at about $n'=14$ and extend out into the neighborhood of $n'=60$ or more. The appearance of lines in these positions is in agreement with the experimentally observed intensities.

Because of the effect of the Boltzmann distribution factor, there are very few molecules in the higher n'' states so that the absence of transitions starting from the higher n'' levels is explained even though their calculated transition probabilities are large.

d. Hydrogen.

In the absorption spectrum of hydrogen all the transitions have the same initial quantum level ($n''=0$) and we should therefore expect Eq. (11) to give a fairly accurate representation of their intensities. The intensity constants for the hydrogen absorption spectra are obtained from the molecular constants given by Richardson and Davidson¹⁴ and are $\alpha=1.786$ and $\delta=4.45$. The agreement of the calculated intensities with the absorption data given by Dieke and Hopfield¹⁵ is shown in Fig. 3. The agreement in this case is not

n'	0	1	2	3	4	5	6	7	8	9
I_0	2	6	8	5	4	8	3	6	4	6
I_c	1.0	7.2	22.5	38.5	39.0	20.7	4.2	0.02	1.2	0.19

Fig. 3. Observed (I_0) and calculated (I_c) intensities for the ultra-violet absorption spectrum of the hydrogen molecule. The initial vibrational state of all of these transitions is the same.

good although it will be seen that the theoretical calculations give about the right number of bands at least. No explanation of these discrepancies can be given but it must be realized that the intensities are in the extreme ultra-violet where it is very difficult to make accurate absorption estimates. Because of the similarity of the higher wave functions one would expect the intensities of the higher observed bands to become gradually smaller rather than to break off suddenly as is shown in the figure. It may be possible too that the fact that a harmonic oscillator was assumed will explain the discrepancies in the bands at the right of the figure.

Although as was stated earlier, we cannot expect very close agreement between emission spectra and the calculated intensities the emission spectra of the $3^1B \rightarrow 2^1S$ band system of hydrogen shows some interesting points. The notation and constants are taken from Richardson and Davidson¹⁴ and we find $\alpha=0.784$ and $\delta=-1.008$. The experimental values are taken from

¹⁴ A. W. Richardson and P. M. Davidson, Proc. Roy. Soc. A125. 35 (1929).

Kapucinsky and Eymers¹⁶ intensity measurements. These measurements are in the visible region and were carefully made by means of a registering microphotometer so that great faith may be had in the results. The experimental and calculated intensities are shown together in Fig. 4. It will be seen in this

$n \backslash n''$	0	1	2	3

figure that good agreement is obtained except at the positions in which n changes by ± 1 units. At these positions the intensities are apparently reversed, that is, the one corresponding to a change in n of $+1$ agrees better in every case with the experimental intensity corresponding to a change of -1 in n and vice versa. No explanation of this fact can be given at the present time.

IV. CONCLUSION

On the basis of wave mechanics the intensity of a spectral line is measured by the integral of the product of the electric moment and the wave functions of the initial and of the final states. It is possible to carry this integration through approximately for vibration electronic transitions in symmetrical diatomic molecules. In this way a formula is developed for the intensity of any band in the electronic vibration spectra of these molecules. The intensities of certain spectral bands of Na_2 , K_2 , I_2 , and H_2 are calculated and in some cases rather good agreement with experiment is obtained. It should be noticed that although there are discrepancies in many of the results the general intensity values and the number of lines to be expected agree well with experiment in all cases in spite of the fact that the important constant (depending upon nuclear separations) varies from -1.01 in the $3'B - 2'S$ band of hydrogen to $+14.9$ in the absorption spectrum of iodine.

The writer wishes to express his sincere appreciation to Professor E Schrödinger for many helpful suggestions and for the privilege of using the facilities of the Institut für theoretische Physik at Berlin. The writer wishes also to thank the University of Pittsburgh for a grant which helped to make his stay in Europe possible.

VIBRATIONAL QUANTUM ANALYSIS OF THE POTASSIUM INFRARED ABSORPTION BANDS

BY W. O. CRANE AND ANDREW CHRISTY

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received June 19, 1930)

ABSTRACT

The heads of the red system of the K_2 molecule have been remeasured, and twenty six new bands have been found. The vibrational constants derived from our measurements are: $\omega_e''=92.64\text{ cm}^{-1}$, $\omega_e''x''=0.354\text{ cm}^{-1}$, $\omega_e'=74.73\text{ cm}^{-1}$, and $\omega_e'x'=0.327\text{ cm}^{-1}$.

The bands of the infrared system of K_2 ($\lambda 7735$ to $\lambda 8850$) have been measured and a new vibrational analysis for this system is given, which removes the objections inherent in the analysis of Ritschl and Villars. The constants for this system, as found by us, are: $\omega_e''=92.64\text{ cm}^{-1}$, $\omega_e''x''=0.354\text{ cm}^{-1}$, $\omega_e'=69.09\text{ cm}^{-1}$, and $\omega_e'x'=0.153\text{ cm}^{-1}$. It is shown that the upper state of each of the two systems dissociates into a normal and a 2P excited atom. The energies of dissociation obtained for the upper levels of the two systems agree to within 0.02 volts, the average value being 2.41 volts. From this average value we obtain for the heat of dissociation of the lower level 0.81 volts, while from the formula $(\omega_e'')^2/4\omega_e'x''$, we obtain 0.75 volts.

THE absorption spectrum of the K_2 molecule thus far investigated contains three band systems: in the blue, $D\leftarrow A^1\Sigma$, ($\lambda 4243$ to $\lambda 4613$), in the red, $C^1\Pi\leftarrow A^1\Sigma$ ($\lambda 6280$ to $\lambda 6925$), and in the infrared, $B^1\Sigma\leftarrow A^1\Sigma$ ($\lambda 7735$ to $\lambda 8850$).

The vibrational analysis of the blue system has been given by Yamamoto^{1,2} The equation of the band heads in terms of half quantum numbers is:

$$\nu = 22970.0 + 61.28(v' + \frac{1}{2}) - 0.24(v' + \frac{1}{2})^2 - 92.54(v'' + \frac{1}{2}) + 0.353(v'' + \frac{1}{2})^2 \quad (1)$$

The red system, $C^1\Pi\leftarrow A^1\Sigma$, was analyzed by Fredrickson and Watson.³ The equation connecting the heads in terms of half quantum numbers is:

¹ H. Yamamoto, Nat. Research Council Japan 5, 146 (1929).

The equation actually given is:

$$\nu = 22954.6 + (61.13n' - 0.24n'^2) - (91.96n'' - 0.32n''^2)$$

The constants for the equation, according to Yamamoto, were obtained by the least square method. However, there must have been some error in the calculation of ω_0'' and $\omega_0'x''$. When the least square method is applied to all the intervals as actually obtained from the heads given in the paper the authors find: $\omega_0''=92.19\text{ cm}^{-1}$ and $\omega_0'x''=0.353\text{ cm}^{-1}$. These values are used in Eq. (1). These corrected values of the constants ω_0'' and $\omega_0'x''$ agree exactly with the constants as derived by the authors from the two other systems.

² See also W. Weizel and U. Kulp, Ann. d. Physik 4, 971 (1930). The analysis of the same system as given by these authors is based on seventeen heads measured by Walter and Barrat, Proc. Roy. Soc. A119, 257 (1928).

³ W. R. Fredrickson and W. W. Watson, Phys. Rev. 30, 429 (1927).

$$\nu = 15377.35 + 74.88(v' + \frac{1}{2}) - 0.30(v' + \frac{1}{2})^2 - 92.35(v'' + \frac{1}{2}) + 0.34(v'' + \frac{1}{2})^2 \quad (2)$$

The infrared system was first photographed by McLennan and Ainslee.⁴ They gave the measurements of nine heads extending from $\lambda 8212$ to $\lambda 8602$. It is mainly with the latter system that this paper deals.

The region of the spectrum from $\lambda 6200$ to $\lambda 8850$ was photographed in the first order of a Rowland concave grating giving a dispersion of 2.632 Å per mm. The vapor was contained in a glass tube 80 cm long heated electrically. The source of light was a 150 watt lamp. In the process of this investigation the heads of the bands of the red system were measured in an attempt to obtain a more accurate equation.

Shortly after this work had begun Ritschl and Villars⁵ published a short note on the vibrational analysis of the infrared system, $B^1\Sigma \leftarrow A^1\Sigma$, giving the following equation, as expressed in half quantum numbers:

$$\nu = 11584.9 + 71.43(v' + \frac{1}{2}) - 0.40(v' + \frac{1}{2})^2 - 91.40(v'' + \frac{1}{2}) + 0.30(v'' + \frac{1}{2})^2. \quad (3)$$

No data or measurements were given in that note and insofar as we know none were given subsequently. This equation has been tested by the authors and, as will be shown later, is probably incorrect.

RESULTS

Red system: In this system twenty six new heads were obtained bringing the total to seventy. These additional bands correspond to transitions involving higher quantum numbers than the bands measured by Fredrickson and Watson.³ With the new measurements the following equation was obtained:

$$\nu = 15377.73 + 74.73(v' + \frac{1}{2}) - 0.327(v' + \frac{1}{2})^2 - 92.64(v'' + \frac{1}{2}) + 0.354(v'' + \frac{1}{2})^2 \quad (4)$$

The new equation is believed to be more accurate since it includes heads of higher quantum numbers than Eq. (2). Table I gives the wave-length and wave-number values for this system. The average observed minus calculated difference is 0.39 cm^{-1} .

Far red system: The far red system contains many more observable heads than the one discussed above. Also, the bands are less clearly differentiated due to the great amount of overlapping throughout the entire system. This overlapping is also responsible for the presence of many faint markings on the plates whose appearance does not show whether they are heads or accidental condensations of lines. In all, two hundred apparent heads have been measured. It is doubtful, however, whether or not all of these are actually heads.

The first step in the investigation was to test the formula of Ritschl and Villars. It was found that a large number of heads could be fitted into this formula if it were modified slightly. It was noticed further that on the basis of the above equation the distribution of the bands within the system was somewhat erratic. The main objections to this formula however were two: (1) the value of ω_e'' , (2) the heat of dissociation derived from their equation for the upper state.

It will be seen that ω_e'' of Eq. (3) differs somewhat from that of Eqs. (1) or (4). Ritschl and Villars did not state the number of heads from which Eq. (3) was derived, but it was thought that when a large number of heads

were included into this system the discrepancy would disappear. Indeed, we have found that the ω_e'' obtained by us, in testing Eq. (3), was 91.92, a difference of 0.72 cm^{-1} from the ω_e'' of Eq. (4), as compared with 1.24 cm^{-1} resulting from the equation as given by Ritschl and Villars. When, however, the value of 92.64 was inserted into Eq. (3) it was found that the deviations were far greater than the experimental accuracy warranted. The heads of the infrared system actually did not fit this modified equation. An attempt was then made to account for the discrepancy by the fact that the theoretical equations are derived for band origins, while in both systems band heads had been used. However with any reasonable assumption as to distance of heads to origins the correction introduced is about 1/100 of the above discrepancy.⁶

The second objection to Eq. (3) is the calculated heat of dissociation of the upper state. It has been assumed that the lowest state of K_2 , $A^1\Sigma$, dissociates into two normal potassium atoms, while the excited state, $C^1\Pi$, dissociates into a normal atom and an excited 2P atom as illustrated in Fig. 1. Birge⁷ using Eq. (2) calculated the heat of dissociation of the upper state as 0.57 volts. From this he derived the heat of dissociation for the lower state as 0.89 volts, by making use of the assumption noted above. Using the more accurate Eq. (4) we obtain for the upper state:

$$A^1\Pi: D' = \frac{(74.73)^2}{4 \times 0.327 \times 8106} = 0.527 \text{ volts} \quad (5)$$

and for the lower state:

$$A^1\Sigma: D'' = \frac{(92.64)^2}{4 \times 0.354 \times 8106} = 0.748 \text{ volts} \quad (6)$$

From Eq. (5) we obtain:

$$H_{\text{red}} = \frac{15377.73}{8106} + 0.527 = 2.424 \text{ volts} \quad (7)$$

where $H = \nu_e + D'$; ν_e being the electronic energy of the system involved and D' the heat of dissociation of the upper level of that system. D'' is not expected to be as accurate as D' since fewer levels are known for the lower state.

Reverting to Eq. (3) of Ritschl and Villars; the lower state of the infrared system is the same as that of the red system i.e., $A^1\Sigma$. Therefore we would expect the upper state to dissociate into one normal and one 2P excited atom, or into a normal atom and an atom with higher excitatoin potential than the atomic 2P state. Calculating D' from Eq. (3) we get:

$$D' = \frac{(71.40)^2}{4 \times 0.40 \times 8106} = 0.393 \text{ volts} \quad (8)$$

⁶ The values of ω_e'' as obtained independently from two different systems by Yamamoto and us agree to within 0.1 percent.

⁷ International Critical Tables, V, 410-418 (1929).

The total energy is:

$$H_{\text{infrared}} = \frac{11584.9}{8106} + 0.393 = 1.822 \text{ volts} \quad (9)$$

as compared with 2.424 volts.

H , as derived from Eq. (9) is too small, and since the first excited state of K is the 2P state, and there is no intermediate atomic state into which the molecule can dissociate the equation necessarily must be wrong. The difference, 0.608 volts, is almost twice as much as D' of Eq. (8) and although

the equation from which the heats of dissociation are obtained may be first approximations, we would not expect that the deviations would be so large.

The equation of Ritschl and Villars was therefore abandoned and combinations between the heads were sought so that the ω_e'' derived from this system would be the same, within experimental error, as those obtained from the blue and the red systems. Such combinations were found, resulting in a new analysis in which 119 heads were included. The equation connecting these heads is:

$$\nu = 11683.58 + 69.09(v' + \frac{1}{2}) - 0.153(v' + \frac{1}{2})^2 - 92.64(v'' + \frac{1}{2}) + 0.354(v'' + \frac{1}{2})^2 \quad (10)$$

In this equation the origin and all the constants are different from those given by Ritschl and Villars. The average observed minus calculated value based on this equation is 0.93 cm.⁻¹. Table II gives the heads of the system and their assigned quantum numbers. The remaining 80 heads have been examined carefully and most of them are apparently accidental condensations of lines.

It is seen from Eq. (10) that the constants of the lower state are exactly the same as those of the red and blue systems.

HEATS OF DISSOCIATION

From the upper level of the red system we obtained $H_{\text{red}} = 2.424$ volts. Calculating D' from Eq. (10) we obtain:

$$B^1\Sigma: D' = \frac{(69.09)^2}{4 \times 0.153 \times 8106} = 0.962 \text{ volts} \quad (11)$$

and

$$H_{\text{infrared}} = \frac{11683.58}{8106} + 0.964 = 2.402 \text{ volts.} \quad (12)$$

The values of H as obtained from two different states agree within 1 percent.

From the blue system, we obtain:⁸

$$D' = \frac{(61.28)^2}{4 \times 0.24 \times 8106} = 0.483 \text{ volts} \quad (13)$$

and

$$H_{\text{blue}} = \frac{22970.0}{8106} + 0.483 = 3.311 \text{ volts.} \quad (14)$$

From the equation $H = \nu_{\text{e(mol)}} + D' = D'' + \nu_{\text{(atom)}}$ we obtain for the excitation potential of the atom $\nu_{\text{(atom)}}$:

$$\nu_{\text{(atom)}} = 3.31 - 0.81 = 2.50 \text{ volts} \quad (15)$$

as compared with

$$5^2S - 4^2S = 2.596 \text{ volts}$$

$$4^2D - 4^2S = 2.658 \text{ volts.}$$

The last two values are within the experimental error involved in Eq. (15). It is probable, however, that the upper state of the blue system is also $^1\Sigma$, which upon dissociating gives a normal atom and a 5^2S atom.⁹

Taking H'' as the mean of the two values in Eqs. (7) and (12) i.e. 2.41 volts we find that¹⁰

$$D'' = 0.81 \text{ volts}$$

On the other hand, from the constants of the lower state we obtain:

$$D'' = 0.75 \text{ volts}$$

a difference of only 0.06 volts between the two values.

⁸ These are essentially the same values as given by Yamamoto.

⁹ Professor Mulliken has pointed out that the lowest state of K_2 , (cf. the corresponding state of Na_2), since it is a singlet state, must be $A^1\Sigma_g^+$. The first excited state is $B^1\Sigma_u$, the second $C^1\Pi_u$ while the third is in all probability a $D^1\Sigma_u^+$. g (gerade) = even, u (ungerade) = odd, in the sense of these terms used by Hund.

¹⁰ We have taken $4^2S - 4^2P$ of the K atom to be 1.608 volts.

In Figure 1 the four $U(r)$ curves for the states A , B , C , and D , are drawn using the formula given by Morse.¹¹ r_0 values were obtained by means of the equation given in the same paper, i.e. $\omega_0 r_0^3 = 3000 \times 10^{-24}$.

The heat of dissociation for the normal state of K_2 was obtained by Carelli and Pringsheim¹² from two somewhat similar methods, the values given by them being 0.63 volts and 0.53 volts. Somewhat later Ditchburn¹³ calculated the heat of dissociation as 0.51 volts.

Fig. 1. $U(r)$ curves for the electronic states A , B , C and D .

In the experiment of Carelli and Pringsheim the vapor pressure of the molecules in thermodynamic equilibrium with the atoms was measured at several different temperatures. However the vapor pressure was not directly measured but was assumed to be proportional to the intensity of the band fluorescence produced when white light was passed through the vapor. The experimental errors involved in measuring the blackening of the plate etc. are rather large. Furthermore the heat of dissociation is obtained from the slope of the equation (first method, the second method is exactly analogous) $\log (IT) = f(1/T)$, where I is the intensity of the band fluorescence and T

¹³ R. W. Ditchburn, Proc. Roy. Soc. **A117**, 486 (1928).

the absolute temperature. It can be shown easily that this method would not give an accurate value of the heat of dissociation. A very slight change in the slope of the line drawn through their points would give a totally different value for the heat of dissociation. The value 0.75 volts is within their experimental error, and it is actually obtained from one of the four curves given in their paper.¹⁴

In Ditchburn's experiment white light was passed through a tube containing potassium vapor and the wave-length of the maximum in the region of continuous absorption was found. Ditchburn finds a maximum absorption at about 5820Å corresponding to 2.12 volts, and interprets this value as being the sum of the dissociation energy of the molecule in the lower state plus the energy required to excite the atom from the 4^2S to the 4^2P state. Since the latter energy is known accurately, he derives the dissociation energy of the molecule as $D'' = 0.5$ volts. The value obtained by him 2.12 volts, is to be compared with the mean value of H obtained from Eqs. (7) and (12), i.e. 2.41 volts. It should be noted that our value corresponds to a transition from the lowest vibrational state of A (refer to Fig. 1) to the threshold value of dissociation in the two upper states B and C , i.e. 2.41 volts corresponds to dissociation at $T = 0^\circ\text{K}$.

The position of the maximum in the continuum depends upon two factors, first, upon the number of molecules in the lower states from which by absorption of light a molecule dissociates, and second, upon the probability of such transitions. The first factor depends upon the temperature of the absorbing gas, while the second depends upon the shape of the $U(r)$ curves of the states involved, here A and C . It is seen from Fig. 1 that the maximum probability of transitions from A to the threshold value of C is from the vibrational level of A corresponding to an energy of 0.45 volts. However we would expect the number of molecules in this particular level to be less than that of lower vibrational states. Hence the maximum will occur for transitions arising from vibrational levels lower than 0.45 volts.¹⁵ Ditchburn's value indicates that the maximum corresponds to transitions from the vibrational level of 0.3 volts. He does not give the temperature at which this experiment was performed, however we can see from Fig. 1 that in general heats of dissociation obtained by measuring the wave-lengths of the region of maximum absorption from states A to C will be too low.

It is with pleasure that the authors acknowledge their indebtedness to Professor W. W. Watson for suggesting this problem and to Professor R. S. Mulliken for his valuable criticism and advice.

THE ROTATIONAL MOTION OF MOLECULES IN CRYSTALS

BY LINUS PAULING

GATES CHEMICAL LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY

(Received May 7, 1930)

ABSTRACT

It is shown by the discussion of the wave equation for a diatomic molecule in a crystal that the motion of the molecule in its dependence on the polar angles θ and ϕ may approach either one of two limiting cases, oscillation and rotation. If the intermolecular forces are large and the moment of inertia of the molecule is large (as in I_2 , for example), the eigenfunctions and energy levels approach those corresponding to oscillation about certain equilibrium orientations; if they are small (as in H_2), the eigenfunctions and energy levels may approximate those for the free molecule, even in the lowest quantum state.

It is found in this way that crystalline hydrogen at temperatures somewhat below the melting point is a nearly perfect solid solution of symmetric and antisymmetric molecules, the latter retaining the quantum weight 3 for the state with $j=1$ as well as the spin quantum weight 3. This leads to the expression

$$S = -n_A R \log n_A - (1 - n_A) R \log (1 - n_A) + n_A R \log 9 + S_{tr},$$

in which S_{tr} is the translational entropy, for the entropy of the solid at these temperatures. At lower temperatures (around 5°K) the solid solution becomes unstable relative to phases of definite composition, and the entropy falls to

$$S = n_A R \log 3 + S_{tr},$$

the entropy of mixing and of the quantum weight 3 for $j=1$ being lost at the same time. Only at temperatures of about 0.001°K will the spin quantum weight entropy be lost.

Gradual transitions covering a range of temperatures and often unaccompanied by a change in crystal structure, reported for CH_4 , HCl , the ammonium halides, and other substances, are interpreted as changes from the state in which most of the molecules are oscillating to that in which most of them are rotating. The significance of molecular rotation in the interpretation of other phenomena is also discussed.

I. INTRODUCTION

THE calculation of the difference in entropy of gaseous molecular hydrogen and crystalline hydrogen has recently been made by Giauque and Johnston.¹ At temperatures between the melting point (14°K) and about 10°K the heat capacity of the solid is well represented by a Debye function with $\beta\nu = 91^\circ$. Assuming the validity of extrapolation to 0°K by means of this function, it is found that the difference in entropy of the solid at 0°K and the gas at standard conditions is 29.7 ± 0.1 E. U. The molal entropy of the gas at standard conditions is given by the Sackur-Tetrode equation as 34.00 E. U., using the band spectrum value of the moment of inertia, and taking into account the symmetry number term ($-R \log 2$), the entropy of mixing of sym-

¹ W. F. Giauque and H. L. Johnston, J. A. C. S. 50, 3221 (1928).

metric and antisymmetric molecules, present in the ratio of $1:3(-1/4 R \log 1/4 - 3/4 R \log 3/4)$, and the nuclear spin quantum weight of the antisymmetric molecules ($3/4 R \log 3$). Thus the molal entropy of ordinary crystalline hydrogen (the metastable mixture of symmetric and antisymmetric molecules in the ratio of $1:3$) at temperatures somewhat below the melting point is found to be 4.3 ± 0.1 E. U. in addition to the translational entropy. In the attempt to account for this deviation from the value zero to be expected from the third law of thermodynamics, it was found necessary to carry through the quantum mechanical discussion of the motion of molecules in crystals.

Before proceeding with this task, it may be illuminating to mention the concept of the motion of a molecule in a crystal which we would form on the basis of classical mechanics. All but six of the degrees of freedom for the molecule can be assigned to represent relative motions of the atoms within the molecule, corresponding to internal oscillations. The six remaining degrees of freedom can be represented by the three coordinates x, y, z of the center of mass of the molecule referred to an arbitrarily chosen set of axes, and the Eulerian angles φ, θ, χ determining the orientation of the molecule with respect to the same axes. In case the forces between atoms in a molecule are much stronger than those between atoms in different molecules, a crystal of the substance may be considered as a first approximation to be a collection of rigid molecules held in a regular arrangement by the rather weak intermolecular forces. Each molecule will remain in the neighborhood of its equilibrium position, the coordinates x, y, z varying through only a small region of values about x_0, y_0, z_0 . Similarly, there will be one or more sets of values of φ, θ, χ for which the potential energy is a minimum, corresponding to equilibrium orientations of the molecule. There are two types of motion then possible for the molecule. If the potential energy for values of φ, θ, χ in the neighborhood of $\varphi_0, \theta_0, \chi_0$ is very small compared with that for other values, the difference being much larger than kT , the average molecule at the temperature T will carry out only small vibrations about its equilibrium orientation. This may be spoken of as oscillation about the equilibrium orientation. But if the potential energy undergoes a total variation smaller than kT , the kinetic energy of the average molecule will suffice to carry it into any orientation, so that the molecule will undergo non-uniform rotation, speeding up as it passes through the equilibrium orientations and slowing down as it goes over the potential maxima. A molecule with a given amount of energy and acted upon by a given potential would according to the classical theory assume a succession of orientations corresponding either to one or to the other of these possibilities, oscillation or rotation.

The introduction of the quantum mechanics does not require this picture to be changed essentially. The allowed states of the system can approximate either of two extremes, oscillation and rotation, or can lie between these extremes, approximating neither more closely than the other. For with the quantum mechanics, in contradistinction to the classical theory, the transition from one extreme to the other is unbroken.

II. THE DIATOMIC MOLECULE IN A CRYSTAL

In Fig. 1 there is shown the structure of the orthorhombic crystal iodine as determined with the use of x-rays.² The atoms are joined in pairs to form molecules by strong shared-electron-pair bonds, and the molecules are

Fig. 1. The arrangement of atoms in one layer in a crystal of iodine. It is seen that the atoms are in groups of two (the molecules I_2) which are oriented by the intermolecular forces.

grouped together in such a way that the figure axis for each assumes a definite orientation. This is the equilibrium orientation, with the polar angle $\theta = 0$, say. The symmetry of the molecule requires that there also be another equilibrium orientation at $\theta = \pi$.

Let us consider a diatomic molecule in such a crystal. As a first approximation we may neglect the translational oscillations of the molecule under consideration and both the translational and rotational motion of the other molecules in the crystal. The wave equation then may be written

$$\nabla^2 \psi + \frac{8\pi^2 I}{h^2} (W - V) \psi = 0, \quad (1)$$

in which I is the moment of inertia of the molecule and $V = V(\theta, \varphi)$ is a potential function representing the averaged interaction of the molecule with surrounding molecules. The simplest form that can be given this function and have it represent a diatomic molecule with two equilibrium orientations is

$$V = V_0(1 - \cos 2\theta), \quad (2)$$

Fig. 2. The potential function $V = V_0(1 - \cos 2\theta)$.

in which V_0 is a constant. This potential function is shown in Fig. 2. The wave equation then becomes

$$\frac{1}{\sin^2 \theta} \frac{\partial^2 \psi}{\partial \phi^2} + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \sin \theta \frac{\partial \psi}{\partial \theta} + \frac{8\pi^2 I}{h^2} (W - V_0 + V_0 \cos 2\theta) \psi = 0. \quad (3)$$

² P. M. Harris, E. Mack and F. C. Blake. *I. A. C. S.* **30**, 1583 (1928).

The characteristic value equation in θ obtained from this has not been solved except for limiting cases. The corresponding problem in a plane has, however, been fully treated. If the molecule were restricted to motion in a plane the wave equation would be

$$\frac{d^2\psi}{d\theta^2} + \frac{8\pi^2 I}{h^2} (W - V_0 + V_0 \cos 2\theta) \psi = 0 \quad (4)$$

or, writing

$$\alpha = \frac{2\pi^2 I}{h^2} (W - V_0)$$

$$q = \frac{\pi^2 I V_0}{2h^2},$$

$$\frac{d^2\psi}{d\theta^2} + (4\alpha + 16q \cos 2\theta) \psi = 0. \quad (5)$$

Fig. 3. The characteristic values for the six lowest Mathieu functions.

This equation is Mathieu's equation in the usual form.

The requirement that ψ be periodic in θ with the period 2π leads to the functions known as Mathieu functions.³ These are usually designated by the symbols ce_0 , se_1 , ce_1 , se_2 , ce_2 , etc. The functions and the corresponding characteristic values of α as functions of q have been evaluated by Goldstein.⁴ The energy values for the five lowest states are shown in Fig. 3. It is seen

³ E. Mathieu, *Liouville's Jour.* **13**, 137 (1868); Whittaker and Watson, "Modern Analysis," pp. 404-428. E. U. Condon, *Phys. Rev.* **31**, 891 (1928), pointed out that the Mathieu functions of even order are the eigenfunctions for the plane pendulum.

⁴ S. Goldstein, *Trans. Cambridge Phil. Soc.* **23**, 303 (1927).

that for $q=0$ Eq. (5) reduces to the equation for the plane rotator, with energy levels $W_m = (m^2 h^2 / 8\pi^2 I)$. For q large the eigenfunction ψ is appreciably different from zero only for values of θ close to 0 and π , and approximates a combination of Hermite orthogonal functions, the eigenfunctions for the harmonic oscillator. The energy levels for this case are $(n+1/2) h\nu_0$, in which $\nu_0 = h(2q)^{1/2} / \pi I$. Each energy level shows two-fold degeneracy, the corresponding eigenfunctions being approximately

$$\frac{1}{2^{1/2}} \{ \psi_n \theta / \theta_0 + \psi_n (\theta - \pi) / \theta_0 \} \quad \text{and} \quad \frac{1}{2^{1/2}} \{ \psi_n \theta / \theta_0 - \psi_n (\theta - \pi) / \theta_0 \},$$

in which $\psi_n(\theta/\theta_0)$ and $\psi_n((\theta-\pi)/\theta_0)$ represent Hermite orthogonal functions of the indicated arguments, and θ_0 is given by the equation $h\nu_0/2 = V_0\theta_0^2$.

This can be used as the basis of a perturbation treatment of the problem, using the method of variation of constants,⁵ as in the treatment of aperiodic phenomena.⁶ It is found that in case it were possible to carry out an experiment to determine whether the molecule were undergoing vibrations about $\theta=0$ or about $\theta=\pi$, with the use of a method of investigation involving an interaction unsymmetrical in the two atoms composing the molecule, the probability of observing the molecule in one orientation rather than the other would vary in a way corresponding to the molecule's changing end for end with a frequency given by the separation of adjacent energy levels (ce_0 and se_1 , ce_1 and se_2 , etc) divided by h . Reference to Fig. 3 shows that this frequency is very small for q large, justifying the interpretation of the corresponding states as oscillational states, the molecule oscillating about an equilibrium orientation and changing end for end only rarely. But for q small this frequency becomes large, approaching the principal frequency of motion of the molecule; then we say that the molecule is rotating, its rotation being made somewhat non-uniform through interactions with other molecules. The energy levels in this case approximate those for the free plane rotator, and their behavior for small values of q can be conveniently followed by perturbation methods using the rotator eigenfunctions as zeroth order eigenfunctions.

These considerations, involving a hypothetical investigation of the orientation of the molecule, are, while illuminating, not essential to the discussion of the type of motion of the molecule. We can define the motion of the molecule in a given state as oscillational in case the eigenfunction for that state can be closely approximated by a combination of Hermite functions and the energy of the state is given approximately by $(n+1/2) h\nu_0$. For rotational motion the eigenfunction and energy level should approximate those for a free rotator. This definition is equivalent to that given above: the study of Goldstein's Fourier series representation of the Mathieu functions shows that the transition of the eigenfunctions from approximation to Hermite

⁵ P. A. M. Dirac, Proc. Roy. Soc. A112, 661 (1926); J. C. Slater, Proc. Nat. Acad. 13, 7104 (1927); M. Born, Zeits. f. Physik 40, 172 (1926).

⁶ See the clear exposition given the process of radioactive decomposition by M. Born, Zeits. f. Physik 58, 306 (1929).

functions to approximation to sines and cosines takes place rather sharply at the value of q where the separation of adjacent energy levels becomes appreciable. A similar treatment can be applied to the spatial rotator with two potential minima. The discussion of the qualitative course of the energy levels and the nature of the eigenfunctions is similar to that given above, and a detailed treatment is not needed for our purposes.

III. ROUGH CRITERIA FOR OSCILLATION AND ROTATIONAL MOTION

Let us tentatively assume that the motion is oscillationa. Then we can approximate the lower part of $V(\theta) = V_0(1 - \cos 2\theta)$ by a parabola by expanding in powers of θ and $\theta - \pi$ obtaining $-2V_0\theta^2$ and $-2V_0(\theta - \pi)^2$ as the expansions in the neighborhood of $\theta = 0$ and $\theta = \pi$. These correspond to energy levels

$$W_n = (n + 1)h\nu_0, \quad n = 0, 1, 2, 3, \dots \quad (6)$$

for the two-dimensional harmonic oscillator, with

$$\nu_0 = \frac{1}{\pi} \left(\frac{V_0}{I} \right)^{1/2}. \quad (7)$$

In case that $W_n = (n + 1)h\nu_0$ is less than $2V_0$, the top of the potential hill separating the two-valleys, the molecule will change orientation only rarely. (The exceptional case with V_0 and n small for which there is a large probability of the molecule turning end for end even when its energy is not sufficient to carry it over the hill, is discussed later). But for W_n larger than $2V_0$ the motion will be rotational. Thus we obtain the following criteria:

$$\begin{aligned} n + 1 &< \frac{2\pi(IV_0)^{1/2}}{h}, & \text{oscillational motion,} \\ n + 1 &> \frac{2\pi(IV_0)^{1/2}}{h}, & \text{rotational motion.} \end{aligned} \quad (8)$$

The uncertain quantity of these expressions is V_0 . A rough value for it can be obtained from the observed heat capacity of the solid. If the molecules oscillate about equilibrium orientations the molal heat capacity would be given as a first approximation by the sum of a Debye function of parameter $\beta\nu$, corresponding to the translational oscillations, and twice an Einstein function of parameter $\beta\nu_0 = h\nu_0/k$, with ν_0 the characteristic frequency of Eq. (7). It is found that such a curve does not give a very close fit with observed heat capacities since the model is too greatly simplified; but the heat capacity curve does show that $\beta\nu$ and $\beta\nu_0$ are nearly the same for many substances and a rough value for them can be obtained by taking three times the temperature at which the heat capacity reaches 5 cal/mole degree; that is, half the high-temperature value for five degrees of freedom.⁷ Values of

⁷ This procedure is based on the fact that an Einstein function reaches half its maximum value at the temperature $0.33\beta\nu_0$.

TABLE I.

Molecule	$\beta\nu_0$	Θ	n_0+1	V_0	Heat of fusion and transition
				cal/mole	cal/mole
I ₂	75°	0.053°	350	25000	4000
N ₂	65°	2.33°	7.0	450	222
O ₂	70°	2.06°	8.5	600	306
CO	75°	2.65°	7.1	500	354
CH ₄	55°	8.5°	1.6	90	242
HCl	160°	14.9°	10.7	1700	760
HBr	125°	11.9°	10.5	1300	803
HI	105°	9.2°	11.4	1200	897
H ₂	<135°	82°	<0.4	<56	28

$\beta\nu_0$ for several substances⁸ are given in Table I, together with the characteristic temperature for rotational degeneracy, Θ , which is related to the moment of inertia I (obtained from band spectral data) by the equation

$$\Theta = \frac{h^2}{8\pi^2 I k} \quad (9)$$

The heat capacity of solid hydrogen provides no information regarding $\beta\nu_0$ for H₂. An upper limit for $\beta\nu_0$ can, however, be found in the following way. It is seen that for many substances the total heat change accompanying transitions and fusion is about equal to $V_0/2$ (compare columns 6 and 7 of Table I). Assuming this to hold for H₂, we find $V_0 = 56$ cal/mole, which, from the trend of the ratio $V_0/\Delta H$ with molecular weight, can be accepted as a maximum value. This corresponds to $\beta\nu_0 < 135^\circ$. The approximate constancy of $\beta\nu_0$ in the series I₂, O₂, N₂ suggests a value of this order of magnitude for H₂ also; it and derived quantities are included in Table I.

In terms of $\beta\nu_0$ and Θ the criteria 8 become

$$n + 1 < \beta\nu_0/4\Theta, \quad \text{oscillational motion,} \quad (10)$$

$$n + 1 > \beta\nu_0/4\Theta, \quad \text{rotational motion.}$$

The transition from oscillational to rotational motion should occur for $n = n_0$, with

$$n_0 + 1 = \frac{\beta\nu_0}{4\Theta} \quad (11)$$

Values of n_0+1 are given in Table I. There are also included data for unsymmetric molecules such as HCl. For these a reasonable potential function

⁸ Since these calculations were made some direct verification of them has been provided by the work of L. Vegard (Nature **125**, 14 (1930)) who has obtained spectra from solid nitrogen at very low temperatures involving an electronic transition, a change in oscillation within the molecule, and an additional energy change corresponding to frequencies of 40 cm⁻¹ and 69 cm⁻¹ which he interprets as oscillational jumps for the molecule in the lattice. One of these frequencies probably is the frequency of rotational vibration of the molecule. 40 cm⁻¹ and 69 cm⁻¹ correspond to $\beta\nu_0 = 57^\circ$ and 99° respectively, the first of which is in good agreement with the rough value 65° of Table I.

is $V = V_0(1 - \cos \theta)$, corresponding to an electric dipole in a uniform field. This leads to a transitional value n_0 given by

$$n_0 + 1 = \frac{\beta v_0}{\Theta}. \quad (12)$$

For CO it is doubtful as to whether 11 or 12 is more nearly applicable; the former has been used.

The value $n_0 + 1 < 0.4$ found for H_2 shows that *even in the lowest state* the molecules are rotating freely, the intermolecular forces producing only small perturbations from uniform rotation. Indeed, the estimated $\beta v_0 < 135^\circ$ corresponds to $V_0 < 28 k$, which is small compared with the energy difference $164 k$ of the rotational states $j=0$ and $j=1$, giving the frequency with which the molecule in either state reverses its orientation. The perturbation treatment shows that with this value of V_0 the eigenfunctions and energy levels in all states closely approximate those for the free spatial rotator.⁹

The other extreme is provided by I_2 , for which the transition from oscillation to rotation takes place at about $n = 300$. At the melting point the molecules are in states with $n = 10$ or 15 , so that there are no rotating molecules in this crystal. This agrees with the fact that equilibrium positions for the atoms have been found by x-ray methods.

The remaining substances form intermediate cases, the molecules in lower states oscillating and in higher states rotating. Whether the transition to rotational states takes place in the main before the crystal melts will be considered in Section V.

IV. CRYSTALLINE HYDROGEN AND ITS ENTROPY

In ordinary crystalline hydrogen there are three molecules with $j=1$ for every one with $j=0$. The eigenfunctions for these molecules approximate those for free molecules, namely

$$\begin{aligned} j = 0, \psi_0 &= 1/(4\pi)^{1/2}, \\ j = 1, \psi_1 &= (3/4\pi)^{1/2} \cos \theta, (3/4\pi)^{1/2} \sin \theta \cos \phi, (3/4\pi)^{1/2} \sin \theta \sin \phi, \end{aligned} \quad (13)$$

in terms of angles θ and ϕ relative to an arbitrary coordinate system. These rotating molecules interact with each other as though they were nearly spherically symmetrical.¹⁰ Hence we expect the crystal to have a close-packed structure—cubic close-packed, say, with molecules at 000 , $0\frac{1}{2}\frac{1}{2}$, $\frac{1}{2}0\frac{1}{2}$, $\frac{1}{2}\frac{1}{2}0$. This agrees with the known cubic symmetry of crystalline hydrogen.¹¹ The

⁹ It is worthy of especial mention that in the state with $j=0$ the molecules are to be considered as rotating when V_0 is sufficiently small (less than the separation of the levels $j=0$ and $j=1$) even though the energy of the state ($\sim V_0$) is not sufficient to carry the molecule over the potential maximum ($2V_0$). This is shown by the close approximation of the corresponding eigenfunction to the lowest tesseral harmonic and by the high frequency of end-for-end interchange given by the perturbation treatment, starting with oscillational eigenfunctions.

¹⁰ The forces holding the rotating molecules result from interpenetration of the molecules, as for the noble gases.

¹¹ The observed density 0.0808 at $11^\circ K$ corresponds to a unit with $a = 5.46 \text{ \AA}$, the distance between adjacent molecules being 3.86 \AA .

x-ray investigation of the crystals should not lead to the determination of atomic positions, but only of molecular positions.

In cubic close-packing each molecule is surrounded by twelve others, whose interaction with the central molecule can be represented by a potential function of cubic point-group symmetry in case that the twelve molecules are spherically symmetrical or oriented at random. The energy change produced by this potential function, f say, is

$$W^1 = \int \int \psi \bar{\psi} \sin \theta d\theta d\phi,$$

which is easily shown by the consideration of the symmetry of f to be the same for all four eigenfunctions. Thus a molecule of symmetrical hydrogen, with $j=0$, has in a crystal the same energy as a molecule of antisymmetrical hydrogen, with $j=1$. As a result the two forms of hydrogen should form a complete series of nearly perfect solid solutions, and, moreover, the energy content of the crystal, aside from rotational energy, should be independent of the composition. This has been verified by the measurements of Clusius and Hiller,¹² who found symmetrical hydrogen to have the same heat capacity and heat of fusion as the 1:3 mixture.

Additional experimental verification that molecules of hydrogen in condensed phases are in states approximating those for free molecules is provided by the Raman effect measurements of McLennan and McLeod.¹³ A comparison of the Raman frequencies found by them and the frequencies corresponding to the rotational transitions $j=0 \rightarrow j=2$ and $j=1 \rightarrow j=3$ (Table II) shows that the intermolecular interaction in liquid hydrogen produces only a very small change in these rotational energy levels.

TABLE II.

Transition	Raman effect	Band spectra
$j=0 \rightarrow j=2$	354 cm^{-1}	347 cm^{-1}
$j=1 \rightarrow j=3$	588	578
$0 \rightarrow 1$ in intramolecular oscillation	4149	4159

These considerations permit a calculation of the entropy of crystalline hydrogen at temperatures somewhat below the melting point. Ordinary crystalline hydrogen, consisting of the symmetrical and antisymmetrical forms in the ratio of 1:3, has an entropy of mixing of $-(1/4)R \log (1/4) - (3/4)R \log (3/4)$, for the solid solution can be considered ideal. The symmetrical molecules have a quantum weight 1 in the normal state, with $j=0$, and the antisymmetrical molecules a quantum weight 9, corresponding to the three rotational eigenfunctions for $j=1$, each of which is associated with any one of the three spin eigenfunctions. This gives a predicted total entropy of the solid at temperatures just below the melting point of

$$S_{H_2} = -\left(\frac{1}{4}\right)R \log \left(\frac{1}{4}\right) - \left(\frac{3}{4}\right)R \log \left(\frac{3}{4}\right) + \left(\frac{3}{4}\right)R \log 9 + S_{tr} = 4.39 \text{ E. U.} + S_{tr}, \quad (14a)$$

¹² K. Clusius and K. Hiller, *Zeit. f. phys. Chem.* **B4**, 158 (1929).

¹³ J. C. McLennan and J. H. McLeod, *Nature* **123**, 160 (1929).

in which S_{tr} is the translational entropy. This value is in excellent agreement with the experimental value $4.3 \pm 0.1 + S_{tr}$ of Giauque and Johnston.¹⁴ In general a mixture containing n_A mole-fraction of antisymmetric molecules would have

$$S = -n_A R \log n_A - (1 - n_A) R \log (1 - n_A) + n_A R \log 9 + S_{tr}. \quad (14b)$$

At very low temperatures a separation of the three rotational levels with $j=1$ will take place. This is a second-order effect, depending on the mutual orientation of two or more molecules. As an illustration, let us assume that we could obtain a crystal of pure antisymmetric hydrogen. At temperatures not too near 0°K the molecules would be in cubic close-packing, and an arbitrary molecule could be represented by any one of the three eigenfunctions with $j=1$. But there are possible states of the crystal somewhat more stable than those in which the three rotational eigenfunctions with $j=1$ are represented by random molecules. Thus if each molecule were in the state with $j=1$, $m=0$, corresponding to the eigenfunction $(3/4\pi)^{1/2} \cos \theta$, with θ referred to trigonal axes which for the various molecules are oriented as are the figure axes of CO₂ in crystals of this substance, then the energy of the crystal would be less than that of a crystal in which the three eigenfunctions with $j=1$ were represented at random. In crystalline CO₂ each molecule is surrounded by twelve others, of which the six in the equatorial plane point towards the central molecule, bringing six oxygen atoms to within 3.25 Å, while the other six molecules place oxygen atoms 4.12 Å away. As a result the stable orientation for the central molecule is along the trigonal axis. The distribution function $\psi^2 = 3/4\pi \cos^2 \theta$ for a hydrogen molecule with $j=1$ and $m=0$ shows a tendency for the molecule to line up parallel to the axis $\theta=0$, leading to the decreased energy of the CO₂-similar structure described above. Since this is a second-order effect the energy decrease will be considerably smaller than V_0 , of the order of magnitude of $V_0/5$. With V_0 equal to about 28 k at the most, the temperature at which this structure would become stable relative to the random one would be of the order of magnitude of 5°K.

With other simple ratios of symmetric to antisymmetric molecules other structures might become stable at very low temperatures. Since the energy change depends on the interaction of two antisymmetric molecules, which would drop off very rapidly as the molecules were separated, crystals containing only a small fraction of antisymmetric molecules would be unstable, breaking down into two phases, pure crystalline symmetric hydrogen and crystals with n_A (the mole-fraction of antisymmetric molecules) equal to 1, 1/2, or some other simple fraction. This process, involving diffusion of the molecules, might take some time, so that care would be necessary to insure equilibrium in the study of mixtures with n_A small.

The entropy change accompanying this transition is predicted to be

¹⁴ The possibility of the expression of the entropy of hydrogen as the sum of these terms was first noted by Giauque, who observed that it indicated the formation of nearly ideal solid solutions between symmetrical and antisymmetrical hydrogen and the retention of the quantum weight 9 for the latter.

$$S = -n_A R \log n_A - (1 - n_A) R \log (1 - n_A) + n_A R \log 3 \quad (15)$$

corresponding to the restriction of each antisymmetric molecule to one of the three rotational states with $j=1$, and to the removal of the entropy of mixing of the solid solution existing above the transition temperature.¹⁵ The entropy of the crystals then becomes

$$S = n_A R \log 3 + S_{tr}. \quad (16)$$

The discovery of a transition which we identify with this has been reported by Simon, Mendelssohn, and Ruhemann,¹⁶ who measured the heat capacity of hydrogen with $n_A=1/2$ down to 3°K. They found that the heat capacity, after following the Debye curve down to about 11°K, rose at lower temperatures, having the value 0.4 cal/deg., 25 times that of the Debye function, at 3°K. The observed entropy of transition down to 3°K, at which the transition is not completed, was found to be about 0.5 E.U. That predicted by Eq. (15) for the transition is 2.47 E.U.

In crystals for which n_0 is large, such as iodine, the lowest symmetric and the lowest antisymmetric state have practically the same energy and properties, and each corresponds to one eigenfunction only. As a result a mixture of symmetric and antisymmetric molecules at low temperatures will behave as a perfect solid solution, each molecule having just its spin quantum weight, and the entropy of the solid will be the translational entropy plus the same entropy of mixing and spin entropy as that of the gas. This has been verified for I_2 by Giauque.¹⁷ Only at extremely low temperatures will these entropy quantities be lost.

V. THE TRANSITION FROM OSCILLATIONAL TO ROTATIONAL MOTION

A consideration of the values of n_0 for CH_4 , N_2 , O_2 , and the hydrogen halides indicates that these molecules oscillate at low temperatures but go over mainly to rotational states before the melting point is reached. This process should be accompanied by thermal phenomena, as is shown by the following argument. With $n < n_0$ the eigenfunctions in θ and ϕ change only slightly as n is increased; the probability function $\psi\bar{\psi}$, with maxima in the neighborhood of the equilibrium values of θ and ϕ , falls off rapidly from these maxima, and increase in n causes only some spread, corresponding to larger amplitudes of oscillation. But a radical change takes place as n goes through the transition value. The eigenfunctions change completely in nature, becoming much more nearly constant, as may be verified by a study of the Fourier series coefficients given by Goldstein for the Mathieu functions. This change increases the repulsive forces between molecules, and tends to spread the crystal lattice

¹⁵ The entropy $n_A R \log 3$ arising from the three spin eigenfunctions for antisymmetrical molecules will be lost only at temperatures of the order of magnitude of 0.001°K, at which the very small nuclear interaction energy would become appreciable. It may be pointed out that the magnitude of the interaction energy with other molecules for the three states with $j=1$ as compared with the spin-rotation interaction energy is such as not to permit coupling of j and the spin moment to form a resultant.

¹⁶ F. Simon, K. Mendelssohn, and M. Ruhemann, *Naturwiss.* 18, 34 (1930).

¹⁷ Personal communication.

as soon as an appreciable number of molecules have begun to rotate. But spreading the lattice decreases the forces between molecules and decreases $\beta\nu_0$ and V_0 , so that more molecules can rotate. The effect builds up to give a transition, which often is not accompanied by an essential change in the structure of the crystal. The transition is usually not sharp, but covers a range of temperature of several degrees, and is foreshadowed on the low temperature side by an abnormal increase in heat capacity.

Such a transition is shown by methane.¹⁸ The heat capacity rises rapidly from 18°K to a very sharp maximum (over 48 cal/mole deg.) at 20.4°, and then drops sharply to 4.6 cal/mole deg. at 22.8°. The temperature of transition agrees with the low value (about 1) predicted for n_c . A methane crystal between 20° and 90.6°K (the melting point) would be described as consisting of rotating molecules in cubic close-packing;¹⁹ below 20° the tetrahedral molecules oscillate about equilibrium orientations. It would be very interesting to have Raman effect or infrared spectral data for solid methane; above 20° the lines should very closely approximate the rotation lines for the gaseous molecules, and below that temperature should show pronounced changes, the frequencies of the lines increasing and tending to become constant as the motion approaches harmonic oscillation.

The course of the heat capacity curves also indicates that the transitions shown by N₂ and O₂ at 35.4° and 43.76° respectively are accompanied by the setting in of rotation of the molecules. This is supported by the known crystallographic symmetry of the high temperature forms; nitrogen cubic (indicating cubic close-packing of N₂ molecules) and oxygen hexagonal (indicating hexagonal close-packing).

The gradual transitions shown²⁰ by HCl (at 98°K), HBr (at 89°, 113°, and 117°K), and HI (at 70° and 126°K) are to be given a similar interpretation.²¹ Each of the successive transitions in HBr and HI may be connected with incipient rotation about one crystal axis and the expansion of the crystal along that axis alone. In every case freely rotating molecules would assume a close-packed arrangement (cubic close-packing of molecules has been found with x-rays by Simon and Simson²² for the high temperature form of HCl); on cooling below the temperature at which oscillation sets in the molecules may merely orient themselves, giving a structure similar to that of CO₂, for example, or the orientation may be accompanied by a change of position of molecular centers. That this takes place for HCl is indicated by the low symmetry of the low-temperature form shown by Simon and Simson's powder photographs.

¹⁸ K. Clusius, *Zeits. f. phys. Chem.* **B3**, 41 (1929).

¹⁹ J. C. McLennan and W. G. Plummer, *Phil. Mag.* **7**, 761 (1929), have found that powder photographic data indicate cubic close-packing of the molecules.

²⁰ W. F. Giaque and R. Wiebe, *J. Am. Chem. Soc.* **50**, 101 (1928); **50**, 2193 (1928); **51**, 1441 (1929).

²¹ Giaque and Wiebe suggested essentially this explanation, writing "The results suggest the following possibility: the transition starts as a changing thermal equilibrium between energy states of the hydrogen iodide molecule, both in the same crystal lattice, but when a sufficient concentration of the higher energy state has been reached, the system becomes unstable and changes to a new crystalline form."

²² F. Simon and C. v. Simson, *Zeits. f. Physik* **21**, 168 (1924).

It is predicted that the dielectric constants of solid HCl, HBr, and HI at temperatures just below the melting points will be very high and dependent on the temperature, the values being given by Debye's theory of the orientation of electric dipole molecules; while the low-temperature forms will have low dielectric constants nearly independent of the temperature.

In general it is to be expected that rotational motion of molecules and complex ions of sufficiently low moment of inertia will set in below the melting point of the crystals. This condition of low moment of inertia is satisfied by complexes containing hydrogen atoms and one heavy atom. Thus the forces orienting the tetrahedral ammonium ion in an ammonium salt are much stronger than those acting on a methane molecule, so that the ion will oscillate until a much higher temperature than 20°K is reached; but this temperature of transition to rotational motion is still considerably below the melting point.

The transitions have been observed. Simon²³ and co-workers found from heat capacity measurements that ammonium chloride, bromide, and iodide show a gradual transition covering about a 10° range in the neighborhood 240°K, the nature of the phenomenon not depending essentially on the anion.²⁴ X-ray studies showed the crystal structure to be the same before and after the transition, which is accompanied by a small volume change, less than 1%. These investigators attribute the transition to the ammonium ion, but make no other suggestions as to its nature. The observed phenomena are just those expected to accompany the transition from oscillation to rotation of the ammonium ion, however. The increase in the transition temperature in the series NH₄I (-42.5°C), NH₄Br (-38.0°C), NH₄Cl (-30.4°C) further shows the expected effect of increasing interionic forces accompanying decreasing anion radius.²⁵

The rotation of the ammonium ion in salts at ordinary temperatures provides justification for the customary treatment of the ion as spherically symmetrical in the theoretical discussion of the structure of ionic crystals. Further, the rotation of molecules such as NH₃ and H₂O about symmetry axes accounts for the fact that these molecules occupy positions in crystals with symmetry elements not compatible with those of the non-rotating molecule. Thus in Ni(NH₃)₆Cl₂ the NH₃ molecules lie on four-fold axes, and in alum the H₂O molecules on three-fold axes. The rotation of the molecules,

²³ F. Simon, *Ann. d. Physik* **68**, 263 (1922); F. Simon and C. v. Simson, *Naturwiss.* **38**, 880 (1926); F. Simon, C. v. Simson, and M. Ruhemann, *Zeit. f. phys. Chem.* **129**, 339 (1927).

²⁴ A very small hump in the heat capacity curve at -30° was also found for ammonium fluoride; the interpretation of this is uncertain (the structure of this crystal is not the same as that of the other ammonium halides).

²⁵ Small maxima in the heat capacity curves of organic compounds are probably often due to the transition from oscillational to rotational motion of a part of the molecule. Thus the maxima shown by *o*-xylene, *m*-xylene, and hexamethylbenzene (reported by H. M. Huffman, G. S. Parks and A. C. Daniels, *J.A.C.S.*, **52**, 1547 (1930)) would be attributed to the rotation of the methyl groups, which have a low moment of inertia and can rotate about the single bond holding the group to the rest of the molecule. *p*-xylene shows no maximum, indicating that the orienting forces on the methyl group are larger, raising the transition temperature above the melting point.

however, gives them an effective infinite symmetry axis, which is compatible with these positions.

The possibility of rotation introduces considerable uncertainty in the conclusions reached by Hendricks²⁶ in regard to the nature of the aliphatic carbon chain. From the x-ray study of crystals of the mono-alkyl substituted ammonium halides he found that in a number of these crystals the alkyl ammonium ion lies on a four-fold axis of symmetry, a result which apparently excludes the usual staggered chain of carbon atoms, and which caused him to suggest that the chain really is straight. But the moment of inertia of a staggered chain about an axis along the chain would be very small, and we would expect rotation about this axis at ordinary temperatures, giving the chain an effective infinite symmetry axis, which is compatible with the x-ray data. Accordingly, Hendricks' investigation does not require that the staggered aliphatic chain be given up.²⁷

It has been found by Lyons and Rideal that solid unimolecular films on water of long chain hydrocarbons with polar ends exist in two possible forms, one with an area of 20.6\AA^2 per molecule, and the other, stable at higher temperatures, with an area of 26.2\AA^2 per molecule.²⁸ These authors suggest²⁹ that in the more compact form the staggered chains are interlocked, and fit together more closely than at higher temperatures when interlocking is not effective. This explanation is made somewhat more precise by the application of the considerations discussed in this paper. At low temperatures interlocking does take place, the molecules oscillating about certain equilibrium orientations. With increasing temperature rotation sets in, and the film expands; in this state the molecules would be well represented as circular cylinders with a radius equal to the maximum radius of the staggered chain. The phenomenon is exactly analogous to that giving rise to gradual transitions in crystals.

In molecules C_2X_6 , such as ethane, C_2H_6 , there exists the possibility of the two ends of the molecule rotating or oscillating relative to each other. In case that X is a large atom, as in C_2I_6 , the interaction of the two ends of the molecule will be large, and they will carry out small oscillations about the relative orientation in which the atom groups fit closely together, the six atoms X defining the corners of an octahedron. But in C_2H_6 the interaction of the two ends of the molecule will be small, and they will rotate freely about the single bond connecting the carbon atoms, with a frequency which is simply related to the rotational frequency of the entire molecule about its figure axis. The determination of the energy levels characteristic of this motion for molecules of this type, by means of Raman effect or infrared measurements, would permit the evaluation of the potential energy of the molecule as a function of the relative orientation of its ends.

I acknowledge with gratitude the inspiration and assistance received through conversations with Professor W. F. Giaque of the Chemistry Department of the University of California.

DEFLECTION OF ELECTRONS BY A MAGNETIC FIELD ON THE WAVE MECHANICS

BY LEIGH PAGE

SLOANE PHYSICAL LABORATORY, YALE UNIVERSITY

(Received June 26, 1930)

ABSTRACT

The wave equation for a stream of electrons passing through a uniform magnetic field is solved and the characteristic functions discussed. The motion at right angles to the field is found to be completely quantized.

The current density is investigated, and the mean square and mean fourth power radii of curvature found for each quantum state. The mean square radius of curvature is found to be the same for all quantum states of the same energy and identical with that predicted by the classical theory.

The mean radius of curvature is determined by interpolation and is found to be less than that predicted by the classical theory. Therefore values of e/μ calculated by means of the classical formula from measured values of the mean radius of curvature should be too large. The error is estimated and found to be of the same general magnitude as the discrepancy between the results of deflection experiments and those of spectroscopic measurements.

IN his review of the probable values of the general physical constants, Birge¹ gives for the best values of the ratio of charge to rest-mass of the electron:

$$\begin{aligned} e/\mu &= (1.769 \pm 0.002) (10)^7 \text{ abs e.m.u. from deflection experiments,} \\ &= (1.761 \pm 0.002) (10)^7 \text{ " " " from Zeeman effect,} \\ &= (1.761 \pm 0.001) (10)^7 \text{ " " " from H and He spectra.} \end{aligned}$$

The discrepancy between the value obtained from deflection experiments on the one hand and those obtained from spectroscopic evidence on the other is four times the probable error of the former, indicating that the difference is real and not merely the result of accidental errors. Now the value of e/μ obtained from deflection experiments is calculated on the classical electrodynamics, whereas the others are based on quantum theory. Therefore it is important to examine the Schrödinger theory of the motion of a stream of electrons in a uniform magnetic field in order to ascertain whether or not it introduces a correction into the classical formula for the radius of curvature r of the circular path of the electrons about the magnetic lines of force. This problem has been investigated by Alexandrow² on the basis of Dirac's theory. His second order wave Eq (10) differs from the Schrödinger equation which will be used in this paper only in the value of one of the constant coefficients—a difference which is quite negligible for the large energy values which are to be considered. Alexandrow obtains a solution of the wave equation which is everywhere finite and vanishes at infinity, and concludes that the motion is

¹ R. T. Birge, Phys. Rev. Sup. I, 47 (1929).

² W. Alexandrow, Zeits. f. Physik 56, 825 (1929).

not quantized, all values of the energy being allowed. His solution (11) however, contains the factor

$$e^{(k/2)\log(y+iz)} = r^{k/2} \left(\cos \frac{k}{2} \theta + i \sin \frac{k}{2} \theta \right)$$

in plane polar coordinates. Now, one of the requirements of the wave mechanics is that a solution, to be allowed, must be single valued. Therefore it would seem that $k/2$ in Alexandrow's solution must be an integer, and consequently the energy, which is a linear function of k , can assume only discrete values, indicating that the motion is quantized. In fact it will appear that Alexandrow's solution is just one of a multitude of characteristic functions corresponding to a stream of electrons of assigned energy.

SOLUTION OF THE WAVE EQUATION

The wave equation³ for electrons moving through a magnetic field is

$$-\frac{h^2}{8\pi^2\mu} \nabla \cdot \nabla \psi - \frac{eh}{2\pi\mu ic} \mathbf{a} \cdot \nabla \psi + \frac{e^2 a^2}{2\mu c^2} \psi + \frac{h}{2\pi i} \frac{\partial \psi}{\partial t} = 0, \quad (1)$$

where \mathbf{a} is the vector potential. If the field is uniform and in the X direction

$$\mathbf{a} = -j\frac{1}{2}Hx + k\frac{1}{2}Hy,$$

and if we introduce cylindrical coordinates r, θ, x the wave Eq. (1) becomes

$$\begin{aligned} -\frac{h^2}{8\pi^2\mu} \left\{ \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \psi}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 \psi}{\partial \theta^2} + \frac{\partial^2 \psi}{\partial x^2} \right\} - \frac{ehH}{4\pi\mu ic} \frac{\partial \psi}{\partial \theta} \\ + \frac{e^2 H^2}{8\mu c^2} r^2 \psi + \frac{h}{2\pi i} \frac{\partial \psi}{\partial t} = 0. \end{aligned} \quad (2)$$

Putting

$$\psi \equiv X(x)R(r)e^{-im\theta}e^{-2\pi i(W/h)t},$$

where m must be an integer in order that the solution may be single valued, we are led to the two ordinary differential equations

$$\frac{d^2 X}{dx^2} + \frac{8\pi^2\mu}{h^2} W_x X = 0, \quad (3)$$

$$\frac{d^2 R}{dr^2} + \frac{1}{r} \frac{dR}{dr} + \left\{ \frac{8\pi^2\mu}{h^2} W_{r\theta} - \frac{2\pi eH}{hc} m - \frac{m^2}{r^2} - \frac{1}{4} \left(\frac{2\pi eH}{hc} \right)^2 r^2 \right\} R = 0, \quad (4)$$

W_x being the energy associated with the motion along the lines of force and $W_{r\theta}$ that with the motion in the plane at right angles to the magnetic field.

Equation (3) admits a continuous manifold of allowable solutions⁴ representing a uniform current parallel to the field. Our interest being confined to

³ Condon and Morse, *Quantum Mechanics*, p. 28.

⁴ Condon and Morse, p. 42.

the motion in the plane at right angles to the field, we may put $W_x = 0$, $W_r = W$ without limiting the generality of the solution. Our problem, then, is to find the allowed solutions of (4).

If we put

$$\rho^2 \equiv \frac{2\pi e H}{hc} r^2, \quad w \equiv \frac{4\pi \mu c}{he H} W,$$

(4) simplifies to

$$\frac{d^2 R}{d\rho^2} + \frac{1}{\rho} \frac{dR}{d\rho} + \left\{ w - m - \frac{m^2}{\rho^2} - \frac{1}{4} \rho^2 \right\} R = 0. \quad (5)$$

Making the substitution

$$R \equiv \rho^m e^{-\rho^2/4} V(\rho)$$

in (5), where we are supposing m to be positive, we get

$$\frac{d^2 V}{d\rho^2} + \left(\frac{2m+1}{\rho} - \rho \right) \frac{dV}{d\rho} + (w - 2m - 1)V = 0. \quad (6)$$

This equation can be simplified by changing the independent variable from ρ to x where $x \equiv \rho^2$. Then

$$4x \frac{d^2 V}{dx^2} + 2\{2(m+1) - x\} \frac{dV}{dx} + \{w - 2m - 1\} V = 0. \quad (7)$$

Assuming a series solution of the form

$$V = \sum_p A_p x^p$$

we find on substitution in (7)

$$4p(p+m)A_p = \{2p - w + 2m - 1\}A_{p-1}.$$

Therefore the two independent solutions of the differential equation are ascending series starting with x^0 and x^{-m} , that is, with ρ^0 and ρ^{-2m} . The second is inadmissible since it makes R infinite at the origin. Therefore we have to consider only the series which starts with a constant term. The successive coefficients are related by the equation

$$A_p = \frac{2p - w + 2m - 1}{4p(p+m)} A_{p-1}. \quad (8)$$

If the series fails to terminate, this relation may be written

$$A_p = \frac{1}{2p} A_{p-1}$$

for large values of p . Hence the function V approaches infinity for x infinite in the same way as

$$A_0 \left[\cdots \frac{\left(\frac{x}{2}\right)^p}{p!} + \frac{\left(\frac{x}{2}\right)^{p+1}}{p+1!} + \cdots \right] = A_0 e^{x^2/2},$$

making R become infinite of the order $e^{x^2/4}$. Consequently the only allowable solutions are those for which the series terminates. We see from (8), then, that

$$w = 2s + 1, \quad (9)$$

where s is a positive integer equal to or greater than m . The motion, therefore, is completely quantized, the energy values being

$$W = \left(s + \frac{1}{2}\right) \hbar \left(\frac{eH}{2\pi\mu c}\right), \quad s = 0, 1, 2, \dots \quad (10)$$

The last factor in (10) is just the frequency of revolution about the lines of force predicted by the classical theory.

Putting (9) into (8)

$$A_p = - \frac{(s-m) - (p-1)}{2p(p+m)} A_{p-1}. \quad (11)$$

It is more convenient to express the wave functions in terms of the quantum numbers s and k where $k \equiv s-m$, in place of s and m . The energy is a function of s alone, and for a given s , k may have any of the values $0, 1, 2, \dots, s$. For $k=0$ the polynomial V is a constant, for $k=1$ it consists of two terms, and so on. In terms of s and k (11) becomes

$$A_p = - \frac{k-p+1}{2p(s-k+p)} A_{p-1}$$

giving

$$V_{s,k} = \sum_{p=0}^k \frac{(-1)^p x^p}{2^p p! (k-p)! (s-k+p)!}, \quad k = 0, 1, 2, \dots, s, \quad (12)$$

and

$$R_{s,k} = A_{s,k} X^{(s-k)/2} e^{-x/4} V_{s,k}, \quad k = 0, 1, 2, \dots, s. \quad (13)$$

Alexandrow's solution of the wave equation is $R_{s,0} e^{-is\theta}$.

THE V POLYNOMIALS

Denote differentiation with respect to x by D . Then by differentiating (12) we find

$$V_{s,k} = -2DV_{s,k+1}. \quad (14)$$

Next we easily prove

$$V_{s,k} = \frac{1}{k! s!} x^{-(s-k)} e^{x/2} D^k [x^s e^{-x/2}], \quad (15)$$

which we can put in neater form if we write

$$X_s \equiv x^s e^{-x/2}.$$

Then (15) becomes

$$V_{s,k} = \frac{1}{k!s!} x^k X_s^{-1} D^k X_s. \quad (16)$$

From (14) and (15) we get the recursion formula

$$[2(s-k) - x]V_{s,k} = 2(k+1)V_{s,k+1} + xV_{s,k-1}. \quad (17)$$

The first four V polynomials are

$$V_{s,0} = \frac{1}{s!},$$

$$V_{s,1} = -\frac{1}{2s!} \{x - 2s\},$$

$$V_{s,2} = \frac{1}{2^2 2! s!} \{x^2 - 4sx + 4s(s-1)\},$$

$$V_{s,3} = -\frac{1}{2^3 3! s!} \{x^3 - 6sx^2 + 12s(s-1)x - 8s(s-1)(s-2)\}.$$

On account of (15) the zeros of $V_{s,k}$ between 0 and ∞ are the zeros of $D^k[x^s e^{-x/2}]$. The latter function vanishes at 0 and ∞ for all k 's less than s . Now $x^s e^{-x/2}$ has one turning point (maximum at $x=2s$). Consequently $D[x^s e^{-x/2}]$ has one zero between 0 and ∞ , and as it vanishes at both limits, it has two turning points. This requires $D^2[x^s e^{-x/2}]$ to have two zeros and three turning points and so on. Consequently $V_{s,k}$ has k zeros between 0 and ∞ for any k less than or equal to s . This means that all the roots of the equation $V_{s,k}=0$ are real and positive.

THE RADIAL FUNCTION

In terms of the quantum numbers s and m the differential Eq. (5) for R is

$$\frac{d^2 R}{d\rho^2} + \frac{1}{\rho} \frac{dR}{d\rho} + \left\{ 2s - m + 1 - \frac{m^2}{\rho^2} - \frac{1}{4} \rho^2 \right\} R = 0. \quad (18)$$

If we put $u \equiv \rho^{1/2} R$ this becomes

$$u'' + \left\{ 2s - m + 1 + \frac{1 - 4m^2}{4\rho^2} - \frac{1}{4} \rho^2 \right\} u = 0.$$

Denoting solutions for the same value of m but different values of s by u_{s_1} and u_{s_2} ,

$$2(s_2 - s_1) \int_0^\infty u_{s_1} u_{s_2} d\rho = 0 \quad (19)$$

showing that the u functions are orthogonal.

To normalize these functions we must determine the arbitrary coefficient $A_{s,k}$ in (13) so that

$$\int_0^\infty u_s^2 d\rho = \frac{1}{2} \int_0^\infty R_{s,k}^2 dx = 1, \quad (20)$$

where x , as before, stands for ρ^2 . Squaring (13) and using (15)

$$R_{s,k}^2 = A_{s,k}^2 x^{s-k} e^{-x/2} V_{s,k}^2 = \frac{A_{s,k}^2}{k!s!} V_{s,k} D^k [x^s e^{-x/2}].$$

Integrating by parts, with the aid of (14),

$$\int_0^\infty R_{s,k}^2 dx = \frac{A_{s,k}^2}{k!s!} \int_0^\infty V_{s,k} D^k [x^s e^{-x/2}] dx = \frac{2^{s-k+1}}{k!s!} A_{s,k}^2.$$

To satisfy (20) it is necessary that

$$A_{s,k} = \frac{1}{2^{(s-k)/2}} (k!s!)^{1/2} \quad (21)$$

and the normalized radial function is

$$\begin{aligned} R_{s,k} &= \frac{(k!s!)^{1/2}}{2^{(s-k)/2}} x^{s-k/2} e^{-x/4} V_{s,k} \\ &= \frac{1}{2^{(s-k)/2} (k!s!)^{1/2}} x^{-(s-k)/2} e^{x/4} D^k [x^s e^{-x/2}]. \end{aligned} \quad (22)$$

Also

$$R_{s,k}^2 = \frac{1}{2^{s-k}} V_{s,k} D^k [x^s e^{-x/2}]. \quad (23)$$

THE CURRENT

The quantity actually measured experimentally is the deflection of the current of cathode rays or electrons. The current density⁵ is given by

$$\begin{aligned} j &= \frac{eh}{4\pi\mu i} (\bar{\psi} \nabla \psi - \psi \nabla \bar{\psi}) - \frac{e^2}{\mu c} a \psi \bar{\psi} \\ &= -\frac{e^2 H}{2\mu c} \left\{ 1 + 2m \left(\frac{hc}{2\pi e H} \right) \frac{1}{r^2} \right\} R^2 r \theta_1 \end{aligned}$$

where θ_1 is a unit vector at right angles to r in the direction of increasing θ . It is clear from the form of this expression that the current lines are circles about the lines of force for all values of the quantum number m . The current between cylinders of radii r and $r+dr$ is

$$j_{s,k} dr = -\frac{eh}{8\pi\mu} \left\{ 1 + 2 \frac{s-k}{x} \right\} R_{s,k}^2 dx \quad (24)$$

⁵ Condon and Morse, p. 30.

in terms of the quantum numbers s, k and $x \equiv \rho^2$.

Since the constant factor appearing in (24) is of no significance for our purposes, let us consider the function

$$\begin{aligned} J_{s,k} &= \frac{1}{2} x^{1/2} \left\{ 1 + 2 \frac{s-k}{x} \right\} R_{s,k}^2 \\ &= \frac{1}{2^{s-k+1}} x^{1/2} \left\{ 1 + 2 \frac{s-k}{x} \right\} V_{s,k} D^k X_s \end{aligned} \quad (25)$$

and

$$\begin{aligned} J_{s,k} d(x)^{1/2} &= \frac{1}{4} \left\{ 1 + 2 \frac{s-k}{x} \right\} R_{s,k}^2 dx \\ &= \frac{1}{2^{s-k+2}} \left\{ 1 + 2 \frac{s-k}{x} \right\} V_{s,k} D^k X_s dx. \end{aligned} \quad (26)$$

First we will calculate the total current

$$I_{s,k} = \int_0^\infty J_{s,k} d(x)^{1/2} = \frac{1}{4} \int_0^\infty R_{s,k}^2 dx + \frac{s-k}{2^{s-k+1}} \int_0^\infty \frac{1}{x} V_{s,k} D^k X_s dx$$

corresponding to each normalized quantum state. The value of the first term on the right is $1/2$ from (20). To evaluate the second we note that if we integrate by parts with the aid of (14)

$$\int_0^\infty V_{s,k-p} D^k X_s dx = \frac{1}{2^{k-p} s!} |D^{p-1} X_s|_0^\infty = 0 \quad (27)$$

provided p is an integer greater than zero and less than k . Now, from the recursion formula (17),

$$V_{s,k} = \frac{s-k+1}{k} V_{s,k-1} - \frac{x}{2k} (V_{s,k-1} + V_{s,k-2}). \quad (28)$$

Consequently

$$\begin{aligned} \int_0^\infty \frac{1}{x} V_{s,k} D^k X_s dx &= \frac{s-k+1}{k} \int_0^\infty \frac{1}{x} V_{s,k-1} D^k X_s dx \\ &= \frac{s(s-1) \cdots (s-k+1)}{k! s!} \int_0^\infty \frac{1}{x} D^k X_s dx. \end{aligned} \quad (29)$$

But

$$\begin{aligned} \int_0^\infty \frac{1}{x} D^k X_s dx &= \int_0^\infty \frac{1}{x^2} D^{k-1} X_s dx = \cdots = k! \int_0^\infty x^{s-k-1} e^{-x/2} dx \\ &= k!(s-k-1)! 2^{s-k}, \end{aligned} \quad (30)$$

and

$$\int_0^\infty \frac{1}{x} V_{s,k} D^k X_s dx = \frac{2^{s-k}}{s-k} \quad (31)$$

Therefore the total current corresponding to each normalized quantum state is

$$I_{s,k} = \frac{1}{2} + \frac{1}{2} = 1 \quad (32)$$

independent of the quantum numbers s and k .

We are primarily interested in the radius of curvature r in the magnetic field of a current of electrons of kinetic energy W . From the defining equation for $x \equiv \rho^2$ and (10) we have

$$r^2 = \frac{2\mu c^2 W}{e^2 H^2} \frac{x}{2s+1} \quad (33)$$

which is to be compared with the formula

$$r^2 = \frac{2\mu c^2 W}{e^2 H^2} \quad (34)$$

of classical electrodynamics. In the experiments of Wolf,⁶ which Birge considers to be the most accurate for the determination of e/μ by the deflection method, s is of the order of magnitude of (10)⁸. Hence we are concerned only with states for which s is very large.

$$J_{s,0} \text{ AND } J_{s,1}.$$

Let us examine more closely the current densities $J_{s,0}$ and $J_{s,1}$ of the first two states of energy corresponding to the quantum number s . The first of these is

$$J_{s,0} = \frac{1}{2^{s+1} s!} \left(1 + 2 \frac{s}{x} \right) x^{s+1/2} e^{-x/2}. \quad (35)$$

Its only zeros are at $x=0$ and $x=\infty$. It has one maximum, at $x=2s$. The radius of curvature of the maximum current density, then, is given by

$$r_m^2 = \frac{2\mu c^2 W}{e^2 H^2} \frac{2s}{2s+1} \quad (36)$$

agreeing almost exactly for large s with the classical value (34). The maximum current density is

$$(J_{s,0})_{\max} = \frac{2^{1/2}}{s!} s^{s+1/2} e^{-s} \quad (37)$$

and in the neighborhood of the maximum we have approximately

$$\frac{J_{s,0}}{(J_{s,0})_{\max}} = e^{-(x-2s)^2/8s} \quad (38)$$

⁶ F. Wolf, Ann. d. Physik 83, 849 (1927).

for large s . Consequently the current density falls to $1/e^{\text{th}}$ of its maximum value at a point $\Delta x = 2(2s)^{1/2}$ to either side of the maximum. For $s = (10)^8$

$$\frac{\Delta x}{x_{\text{max}}} = \left(\frac{2}{s}\right)^{1/2} = 2^{1/2}(10)^{-4}$$

showing that the peak is extremely narrow.

The current density of the next state is

$$J_{s,1} = \frac{1}{2^{s+2}s!} \left\{ 1 + 2\frac{s-1}{x} \right\} (x-2s)^2 x^{s-1/2} e^{-x/2}. \quad (39)$$

Fig. 1.

Zeros occur at $x=0$, $2s$, and ∞ . There are two maxima, at approximately $x = 2s \pm 2(2s)^{1/2} + 1$. The maximum current densities are approximately the same and equal to

$$(J_{s,1})_{\text{max}} = \frac{2^{3/2}}{s!} s^{s+1/2} e^{-(s+1)}. \quad (40)$$

The graphs of the two functions, $J_{s,0}$ and $J_{s,1}$ are sketched in Fig. 1 for large s , the origin being a great distance to the left of the center of the figure.

Evidently the zeros of $J_{s,k}$ between 0 and ∞ are identical with those of $V_{s,k}$. Thus $J_{s,k}$ has k zeros in this interval.

MEAN RADIUS OF CURVATURE

While the mean radius of curvature of each current cannot be evaluated easily on account of radicals appearing in the integrand, the mean square and the mean fourth power radius of curvature are readily obtained. From (26) and (32)

$$\begin{aligned}\overline{\rho^2} = \bar{x} &= \frac{1}{4} \int_0^\infty \{x + 2(s - k)\} R_{s,k}^2 dx \\ &= (s - k) + \frac{1}{2^{s-k+2}} \int_0^\infty x V_{s,k} D^k X_s dx,\end{aligned}\quad (41)$$

and

$$\begin{aligned}\overline{\rho^4} = \overline{x^2} &= \frac{1}{4} \int_0^\infty \{x^2 + 2(s - k)x\} R_{s,k}^2 dx \\ &= \frac{s - k}{2^{s-k+1}} \int_0^\infty x V_{s,k} D^k X_s + \frac{1}{2^{s-k+2}} \int_0^\infty x^2 V_{s,k} D^k X_s dx.\end{aligned}\quad (42)$$

To evaluate the integrals involved, we have, if we integrate by parts with the aid of (14),

$$\begin{aligned}\int_0^\infty x^p V_{s,k} D^k X_s dx &= \frac{1}{2^k} \int_0^\infty x^p V_{s,0} X_s dx - \frac{k p}{2^{k-1} 1!} \int_0^\infty x^{p-1} V_{s,1} X_s dx \\ &+ \frac{k(k-1)p(p-1)}{2^{k-2} 2!} \int_0^\infty x^{p-2} V_{s,2} X_s dx - \dots\end{aligned}\quad (43)$$

For positive integral values of p the series consists of a finite number of terms. Thus for $p=1$,

$$\begin{aligned}\int_0^\infty x V_{s,k} D^k X_s dx &= \frac{1}{2^k} \int_0^\infty \{x V_{s,0} - 2k V_{s,1}\} X_s dx \\ &= \frac{1}{2^k s!} \left[(k+1) \int_0^\infty x^{s+1} e^{-x/2} dx - 2ks \int_0^\infty x^s e^{-x/2} dx \right] \\ &= 2^{s-k+2} [(k+1)(s+1) - ks] = 2^{s-k+2} (s+k+1).\end{aligned}\quad (44)$$

Hence (41) becomes

$$\overline{\rho^2} = \bar{x} = (s - k) + (s + k + 1) = 2s + 1 \quad (45)$$

independent of the quantum number k . Putting this in (33) we find

$$r^2 = \frac{2\mu c^2 W}{e^2 H^2}, \quad (46)$$

which is identical with the classical formula (34). Hence we conclude that the mean square radius of curvature is the same for all quantum states of the same energy and identical with the square of the radius of curvature given by the classical theory.

Next we shall evaluate (42) for the mean fourth power radius of curvature. In this case we need in addition to (44) the integral (43) for $p=2$. The latter is

$$\begin{aligned} \int_0^\infty x^2 V_{s,k} D^k X_s dx &= \frac{1}{2^k} \int_0^\infty \{x^2 V_{s,0} - 4kx V_{s,1} + 4k(k-1) V_{s,2}\} X_s dx \\ &= \frac{1}{2^k s!} \left[\left(1 + \frac{3}{2}k + \frac{1}{2}k^2\right) \int_0^\infty x^{s+2} e^{-x/2} dx - 2ks(k+1) \int_0^\infty x^{s+1} e^{-x/2} dx \right. \\ &\quad \left. + 2ks(k-1)(s-1) \int_0^\infty x^s e^{-x/2} dx \right] \\ &= 2^{s-k+2} [(k+1)(k+2)(s+1)(s+2) - 2k(k+1)s(s+1) + (k-1)k(s-1)s]. \end{aligned} \quad (47)$$

Consequently (42) becomes

$$\begin{aligned} \overline{\rho^4} &= \overline{x^2} = 2(s-k)[(k+1)(s+1) - ks] \\ &\quad + [(k+1)(k+2)(s+1)(s+2) - 2k(k+1)s(s+1) + (k-1)k(s-1)s] \quad (48) \\ &= (2s+1)^2 + 2(2k+1)(2s+1) + 1. \end{aligned}$$

The mean fourth power of the radius of curvature, therefore, increases with increasing k and is greater than the square of the mean square radius of curvature for all quantum states of a given energy. If we average over all k 's from 0 to s we find

$$\overline{\rho^4} = \overline{\tilde{x}^2} = 8s^2 + 10s + 4. \quad (49)$$

DISCUSSION OF RESULTS

The usual experimental method of measuring the deflection of a stream of electrons by a magnetic field involves the determination of the mean radius of curvature rather than the mean square. On account of the slit or slits used to define the stream, we should expect the greatest number of electrons to be in the states for which k is small, for the increase of spread of J with increase in k would prevent electrons in the higher quantum states from passing through the slit system. In the absence of knowledge of the effect of slit width on the distribution of the electrons, no exact quantitative correction to the classical formula can be given. Certain qualitative conclusions may be drawn, however.

To obtain an estimate of the order of magnitude of the mean radius of curvature of the current for quantum number k we can make use of the known values of $\overline{\rho^0}$, $\overline{\rho^2}$ and $\overline{\rho^4}$. Putting $S \equiv 2s+1$, $K \equiv 2k+1$ we have from (32), (45) and (48)

$$\begin{aligned}\overline{\rho^0} &= 1, \\ \overline{\rho^2} &= S, \\ \overline{\rho^4} &= S^2 \left[1 + 2\frac{K}{S} + \frac{1}{S^2} \right].\end{aligned}$$

If the current distribution were perfectly sharp, we would have

$$\log \overline{\rho^n} = An. \quad (50)$$

If K is small compared to S , the values of $\overline{\rho^0}$, $\overline{\rho^2}$ and $\overline{\rho^4}$ show that the spread of the current is small. Hence we can determine the first order correction to (50) by writing

$$\log \overline{\rho^n} = An + Bn^2$$

and determining the constants A and B to fit the values found for the three means. This gives

$$\overline{\rho^n} = S^{n/2} \left[1 + 2\frac{K}{S} + \frac{1}{S^2} \right]^{n(n-2)/8} \quad (51)$$

Consequently interpolation gives for the mean radius of curvature

$$\begin{aligned}\bar{\rho} &= S^{1/2} \left[1 + 2\frac{K}{S} + \frac{1}{S^2} \right]^{-1/8} \\ &\div S^{1/2} \left[1 - \frac{1}{4} \frac{K}{S} \right].\end{aligned}$$

As this is less than $(2s+1)^{1/2}$ the square of the mean radius of curvature is less than the mean of the square. Hence, as e/μ varies inversely with r^2 , the calculation of e/μ by means of the classical formula will give too large a value of the specific charge of the electron. Therefore the error indicated by theory is of the right sign to explain the discrepancy between the results of deflection experiments and spectroscopic measurements.

To estimate the magnitude of the error we need the mean value of K for the electrons passing through the slit. The spread of the current is given by

$$\Delta\rho^2 = \int_0^\infty J(\rho - \bar{\rho})^2 d\rho = \overline{\rho^2} - \bar{\rho}^2 = \frac{1}{2}K.$$

The quantity $\Delta\rho$ measures the effective distance of the current either side of its mean position. It seems reasonable to infer that half the current passes through the slit when $\Delta\rho/\rho$ is equal to the ratio of the half width of the slit to the radius of curvature. Now the ratio of the half width of the slit to the radius of curvature in Wolf's experiments was 0.04 and s was approximately 1.7(10).⁸ So when

$$\frac{\Delta\rho}{\rho} = \frac{1}{2} \left(\frac{K}{S} \right)^{1/2} = 0.04 \quad \text{or} \quad \frac{K}{S} = 0.0032$$

half the current passes through the slit. Putting $S=3.4(10)^8$, $K=10.9(10)^5$ or $k=5.4(10)^5$. Consequently the ratio of the magnitude of each partial current to that of the next of lower index may be taken to be

$$\alpha = (\frac{1}{2})^{1/5.4(10)^5}.$$

The mean value of K , then, is

$$\bar{K} = \frac{1 + 3\alpha + 5\alpha^2 \cdots + (2s+1)\alpha^s}{1 + \alpha + \alpha^2 \cdots + \alpha^s} = 1 + \frac{2\alpha}{1-\alpha} \frac{1-\alpha^s}{1-\alpha^{s+1}} - \frac{2s\alpha^{s+1}}{1-\alpha^{s+1}}$$

$$\doteq \frac{2}{1-\alpha} = 1.56(10)^6.$$

The error in e/μ is that in $1/\bar{p}^2$, that is, $(1/2)\bar{K}/S$. Hence the order of magnitude of the error is

$$\frac{1}{2} \frac{\bar{K}}{S} = 0.0023.$$

As the actual discrepancy between the results of Wolf's deflection experiments and of spectroscopic observations is 0.0045 ± 0.0011 , we conclude that the error indicated by theory is of the correct order of magnitude as well as of the correct sign to account for the observed discrepancy. In view of the very rough calculation of the mean K , the numerical value obtained above cannot be considered as more than an estimate of the magnitude of the error. The agreement with the observed discrepancy is therefore as good as the method of calculation warrants.

The results of this investigation indicate that in measuring e/μ by the deflection method the classical formula is applicable only if (a) the ratio of slit width to radius of curvature is very small, or (b) the method is one in which the mean square of the radius of curvature is measured. In the latter case it makes no difference in what quantum states the electrons may be, for the mean square of the radius of curvature is the same for all states of the same energy and the value of e/μ is given correctly by the classical formula.

ABSORPTION OF X-RAYS BY LITHIUM

BY K. C. MAZUMDER

LONDON, ENGLAND

(Received May 26, 1930)

ABSTRACT

The mass scattering coefficient of lithium has been measured between the wave-lengths 0.587–0.100Å. The results for the long wave-lengths can be expressed by the equation $\mu/\rho = 0.94\lambda^3 + 0.162$. A very rapid bending of the curve towards the axis λ^3 is noticed below the wave-length 0.2Å.

LITHIUM is the lightest element studied in connection with x-ray absorption. Hewlett¹ worked with it twice but did not carry the investigation down to very short wave-lengths. More recently Mertz² attacked the problem afresh but he too, did not go beyond the wave-lengths used by Hewlett. The shortest wave-length used by Hewlett was 0.314 and that by Mertz 0.32Å. Both of these experimenters were engaged in measuring the scattered rays directly. In the present work, a wider range of wave-lengths, 0.587–0.100Å, was used in measuring in the straight-forward way the total absorption coefficient of lithium. The range of wave-lengths was sufficiently long to show that the absorption by even lithium did not follow the simple law $\mu/\rho = K\lambda^3 + \delta/\rho$ for short wave-lengths.

To prevent oxidation of lithium it had to be placed in an air-tight case the wall of which should not absorb any appreciable amount of rays. The scheme adopted in the present work made it unnecessary to measure by separate experiment the amount absorbed by the wall. A somewhat elliptical hole was cut into a steel rod of desired length. The diameter of the rod was equal to the inner diameter of the brass tube through which rays entered the spectrometer. The major axis of the hole was about two-thirds of the diameter of the rod and twice as much as the diameter of the piece of lithium. On either end of the rod was soldered a thick disk of steel with a hole at the center. One of the holes was sufficiently large to allow the lithium rod to be pushed into it. The other hole was so small as to be completely covered by the piece of lithium when it was in the path of the rays. One of the disks had a much larger diameter than the rod so that when the rest of the rod was pushed inside the brass tube the rays had no openings excepting the smaller hole at the center of the disks to enter the spectrometer. Thin pieces of mica were gummed on either end of the rod after the freshly cut lithium was placed inside. This arrangement was completely air-tight and lithium could be kept inside for weeks without any appreciable amount of oxidation taking place. By simply rotating the steel container through 180

¹ Hewlett, Phys. Rev. 17, 284 (1921); 20, 688 (1922).

² Mertz, Phys. Rev. 28, 891 (1926).

degrees it was possible to place the lithium in or out of the path of the rays. The same mica windows were in the path in both positions, so the correction for absorption by the walls of the container was not necessary.

The lithium used was obtained from Professor Lyman who procured it for his spectroscopic work. Professor Bridgman has samples of the same lithium analysed in connection with his high pressure work, only traces of aluminum were detected, the amount being 0.7 of 1 percent. The correction for aluminum was made by means of the equation $\mu/\rho = 15.5\lambda^3 + 0.147$, representing its coefficient of absorption. This equation was suggested by Professor Duane and the writer.³

The amount of the rays absorbed depending greatly upon the wavelengths it was necessary to use two pieces of lithium of lengths 5.3 cm and 2.9 cm, the former was used for the hard rays and the latter for the comparatively soft rays. The agreement between the results was very satisfactory.

In order to make measurements of the coefficient of absorption, the crystal and the ionization chamber were set in corresponding positions. The steel container with the lithium was placed in the brass tube. It was first kept in a position such that the lithium was out of the path of the rays. The ionization current was observed. The lithium was then placed in the path of rays by rotating the container through 180 degrees. The ionization current was again observed. Both of these readings were corrected for the natural leakage of the instrument and for stray radiations. From these two readings the corresponding mass absorption coefficient was calculated by means of the equation $\mu/\rho = (2.30/d.t) \log I_0/I$, d being the density and t , the length of the piece of lithium.

TABLE I.

λ in A	λ^3	μ/ρ	λ in A	λ^3	μ/ρ
0.587	0.202	0.330	0.368	0.0498	0.208
.535	.1529	.300	.315	.031	.192
.482	.112	.262	.2625	.018	.179
.429	.079	.237	.209	.009	.169
.368	.0498	.206	.185	.0063	.160
.473	.108	.263	.159	.004	.148
.421	.0745	.232	.144	.003	.134
			.102	.001	.114 (?)

The first five readings were taken with the shorter piece of lithium and the rest with the longer piece. The curve in Fig. 1 has been obtained by plotting the mass absorption coefficient against the tube of the corresponding wave-length. It is seen that the curve is not a straight line. It bends downwards in the region of short wave-lengths, the bending being noticeable in the neighbourhood of the wave-length $\lambda = 0.2A$. If the straight part of the curve is produced it cuts the axis at about 0.1625. This according to the theory is the mass scattering coefficient. The value obtained from J. J. Thomson's expression is 0.175, assuming that all the three electrons in the lithium atom scatter freely.

³ Duane and Mazumder, Proc. Nat. Acad. Sci. 8, 45 (1922).

The coefficient of λ^3 is found to be 0.94. The following equation represents approximately the mass coefficient of absorption for comparatively long wave-length

$$\begin{aligned}\mu/\rho &= 0.94\lambda^3 + 0.162 \\ &= 80.5 \times 10^{-3}(N^4/A)\lambda^3 + 0.162\end{aligned}$$

Fig. 1. Mass absorption coefficient plotted against cube of corresponding wave-length.

A and N are the atomic weight and atomic number of lithium respectively.

A slight bending is also noticed in the region of long wave-lengths.

In conclusion the writer wishes to thank Professor Duane for the kind interest he took in the work and for the facilities and suggestions he gave in conducting the experiment. This work was carried out in the Jefferson Physical Laboratory, Harvard University in 1923 but for various reasons it could not be published earlier.

WAVE-LENGTH MEASUREMENTS OF GAMMA-RAYS FROM RADIUM AND ITS PRODUCTS*

BY LUVILLE T. STEADMAN

SLOANE PHYSICAL LABORATORY, YALE UNIVERSITY

(Received June 16, 1930)

ABSTRACT

Wave-length measurements.—The wave-lengths of the gamma-rays in the spectrum of Ra, RaB, RaC, and RaD were determined by the method of crystal diffraction. The rays which experienced diffraction on transmission through a crystal of calcite were received in a Geiger counting chamber which was provided with a slit system that could be turned about a pivot situated at the chamber. By turning the crystal a little so that the diffracted rays were not able to enter the chamber, a method was developed for obtaining the background of the intensity curve and the intensities of the γ -rays, and for investigating the intensity of a possible continuous γ -ray spectrum. Practically all the wave-lengths found by other investigators were obtained and good agreement among all the results was noted. In addition, several other short wave-length γ -rays were found, of which the shortest was 0.42 X.U. Four of them were again determined from measurements made with a diamond which also revealed a γ -ray of wave-length 0.17 X.U.

Intensities of the rays.—In general the changes in intensity from one wave-length to another throughout the spectrum corresponded to those given by other workers, but the intensities of the rays were not found to vary as much.

Continuous spectrum.—A determination of the background of the intensity curve showed that no continuous γ -radiation of any appreciable intensity was present. A more precise measurement made at a wave-length of 53.9 X.U. indicated that a continuous spectrum of γ -rays if existing at all raises the background intensity to less than one tenth the height of the least prominent peaks here found. It has already been concluded from indirect reasoning that the continuous γ -ray spectrum is unimportant.

INTRODUCTION

THERE are several methods by which a rough estimate of the hardness of the gamma-radiation from radioactive elements has been obtained. The quantity which characterizes the hardness has been termed the effective wave-length, and its magnitude is closely associated with the wave-length of some line or lines of strong intensity in the source of the radiation. Kohlrausch,¹ Compton,² and Ahmad,³ have applied the x-ray absorption formula, $\mu = AZ + B\lambda^3 Z^4$, to their work on the absorption of γ -rays and have given λ_{eff} , for the hard γ -rays from RaC to be from 14 to 20 X.U. Similar results were obtained from measurements on the intensity of scattered rays by Owen-Fleming-Fage.⁴ The diffraction of γ -rays by a single atom depends

upon the interference between the rays scattered by the electrons grouped close together in a heavy atom. Compton² has found $\lambda_{eff.} = 25$ X. U. by this method. He also obtained a value for $\lambda_{eff.} = 16$ X. U. by calculating the wave-length of the scattered rays from their absorption coefficient.

A quantitative investigation of the various wave-lengths in the γ -ray spectrum of a radioactive element was first made by Rutherford-Andrade.⁵ They used a crystal of rock salt to reflect the rays emitted by the disintegration products of radium contained in an emanation tube. The diffracted rays which emerged from the crystal at definite angles depending on their wave-lengths, were detected by their action on a photographic plate. However, the lines found by them belonged for the most part to the spectra of hard x-rays emitted by the atoms in the source after they had been excited by the nuclear γ -rays of high energy value.

The introduction of the counting method to the study of the high frequency γ -radiation from radium and its products by Kovarik⁶ enabled him to find many of the true nuclear γ -rays. The rays, after reflection by a calcite crystal were detected by means of a Geiger counter.

The problem was also taken up by several investigators^{7,8,9,10,11,12} who employed the β -ray spectrum method which makes use of the photoelectric effect of the γ -rays. Ellis-Skinner in particular give values for the wave-lengths of some twenty-two γ -rays of nuclear origin in RaB+RaC. In addition, relative intensities have been assigned to the lines. The theory in connection with this has been developed by Ellis-Wooster.¹³ They have taken into account the observed intensities of the β -ray groups as indicated by the photographic plate and also the probability of conversion of the γ -rays into β -rays. However, their method for obtaining the wave-lengths and the intensities of the γ -rays is not considered to be as direct and straightforward as that of crystal diffraction.

Recently, Frilley¹⁴ has made some experimental improvements in the method of Rutherford-Andrade and has been able to extend the measurements by means of photographic registration of the γ -rays. He has identified a large number of the wave-lengths obtained by the β -ray spectrum method. Great difficulty has always been experienced when trying to use the photographic plate to find rays of very short wave-length on account of the large quantity of primary radiation coming from the source. A general back-

ground of stray and scattered radiation also makes it hard to distinguish very weak lines.

The general consensus of opinion thus far has been that there is no continuous spectrum for the γ -rays. This view has been arrived at on consideration of the results of several experiments including the counting by Kovarik¹⁵ of the number of γ -rays from RaB to RaC per atom disintegrating, the study of the intensities in the β -ray spectra by Gurney,¹⁶ the measurements by Ellis-Wooster¹³ on the heating effect of the γ -rays from RaB + RaC, and all the work mentioned above on the γ -ray wave-lengths and their intensities. It was concluded that the energy given off in the heating effect when the rays were absorbed in a suitable material could just about be accounted for by the total energy of all the monochromatic rays observed. There was no necessity for postulating a quantity of energy in the form of a continuous radiation. Because of the indirect method of measurement however it has usually been considered that there has been as yet no real proof either for or against the existence of a continuous spectrum.

Fig. 1A. Crystal set.

In view of this fact and in particular because the lines determined by the β -ray spectrum method had not been completely checked by any crystal diffraction method, and in addition because some of the lines found by one observer had not been found by others, it was considered advisable to continue the investigation of these problems using the counting method. The experimental method used in the present measurements differed from that devised by Kovarik principally in the fact that diffraction of the rays was accomplished by transmission through a crystal instead of by reflection from the surface planes. The crystal was not rotated. Consequently there was one less experimental quantity to be determined and the range of the instrument in the direction of short wave-lengths was increased. The author was able to check nearly all the wave-lengths found before and to extend the measurements to several new γ -rays of very short wave-length. Additional direct evidence was obtained which supports the view of the non-existence of a continuous spectrum of any appreciable intensity. The intensity values found for the γ -rays are more or less in agreement with the results of other observers.

EXPERIMENTAL METHOD

The diffraction of a single γ -ray is represented in Fig. 1A. S is a point source of the rays situated on the line SPF which may be considered as a line of reference. The crystal C is placed so that one set of its (1 0 0) planes is parallel to this line and perpendicular to the page. Then, a γ -ray of wave-length λ , coming from S and making an angle θ with the crystal planes, may undergo diffraction during transmission through the crystal, and if so the diffracted ray will pass over the point F . It can be shown from simple geometrical considerations that $FP = PS$ where P is a point at the center of the crystal. Such a ray must satisfy the Bragg formula for diffraction,

$$n\lambda = 2d \sin \theta$$

Fig. 1B. Crystal turned.

Fig. 1C. Diagram showing that the beam of monochromatic rays which passes into the counting chamber may have a width less than that of the slit.

where n is an integer, d the grating space, λ and θ the wave-length and angle of diffraction respectively. As the angles of diffraction concerned with here are all very small it is sufficient to use the formula $n\lambda = 2d\theta$. Furthermore, the cylindrical source that is used has a definite length and diameter and emits a great many rays in all directions; diffraction therefore will be possible for rays of all wave-lengths provided they are incident at the proper angle θ , and they will pass through the image of the source at F . The lead blocks A, B are shown in positions to form a deep slit or channel through which the rays may pass.

If a detector of γ -rays such as a Geiger counter is placed at F , the impulses which are counted will be due to several types of radiation. A considerable

number of γ -rays may pass right through the lead blocks A , B and come either from the source S or from sources of penetrating radiation in the neighborhood. The rays which pass through the deep slit may be diffracted γ -rays satisfying the above expression, rays which are scattered by the crystal and other parts of the apparatus, and also high speed electrons. At very small angles there will be, in addition, a considerable amount of direct radiation coming through the slit system from the source. If the axis of the slit passes through F and makes the angle θ with FPS the γ -rays diffracted at an angle θ are transmitted without absorption. The slit system is pivoted at F .

In Fig. 1B the crystal is shown turned through an angle of a few degrees about an axis perpendicular to the page. The conditions relating to the absorption and scattering by the crystal remain essentially the same for the two cases. Thus it is readily seen that by taking a γ -ray count for both positions of the crystal, one can obtain the background of the spectrum and the intensities of the γ -rays.

APPARATUS

The gamma-ray spectrometer was constructed as shown in Fig. 2. The base plate A , 24 in. by 8 in., was of cast iron and had strengthening ribs on the bottom. The lead blocks used to shield the source at S and to form

Fig. 2. Gamma-ray spectrometer.

the two slit systems were all 15 cm in height and about 8 cm thick, thickness being measured always in a direction along the axis of the instrument. The two blocks B_1 , B_1 placed about 3 mm apart were used to limit the angular width of the incident beam. The spectrometer rested on a stone pier.

The source of γ -radiation was a preparation of radium salt containing 5.002 mg of radium together with its disintegration products. The glass container was 7 mm long and about 1.5 mm inside diameter and, protected by its thin silver casing, was supported so that its long dimension was in the vertical direction. The experiments were concerned mainly with nuclear rays. Since therefore it was desirable to have as few hard x-rays as possible, no other absorbing material was placed between the source and the crystal.

The crystal holder of a Bragg x-ray spectrometer was used to support the crystal and to orientate it in its proper position. The calcite crystal was 7 mm thick, 10 mm wide, and 25 mm high. It was placed with one of its

faces in contact with the plate *D*. The vertical axis of the crystal holder together with the center of the source and the middle of the pivot determines the axis of the instrument. *D* was adjusted parallel to this by means of a straight edge. By turning the holder a little so that the horizontal peg in its edge was no longer in contact with the peg in the grooved disk beneath, the position illustrated in Fig. 1B was obtained. The distances between *S* and *C* and between *C* and *F* were each 20 cm.

A diamond crystal was also used to measure the shortest wave-lengths. Its dimensions were: height 9 mm, width 4 mm, and thickness 2.5 mm. The orientation of the (1 0 0) planes was determined by means of a goniometer. The grating space for the (1 0 0) planes in calcite is given as $3.0288 (10^{-8})$ cm. In the case of the diamond the 4th order reflection was the one used as the (1 0 0) planes give no 1st, 2nd, or 3rd order. For diamond $1/4$ of d_{100} is $0.885 (10^{-8})$ cm.

The steel plate *E* carrying the slit system could be turned in either direction about the 0.5 inch pivot by means of two small pitch screws. Its zero position with respect to the axis of the spectrometer was determined by the scale and vernier. The angular positions of the slit system, however,

Fig. 3. Geiger counter and amplifier.

were measured by means of a lamp and transparent scale fastened to the wall at a distance of 286.48 cm from a lens and mirror *M*. The scale was accurately ruled in millimeters and one could estimate to 0.1 mm which corresponds to an angle of 3.600 sec. of arc. Since the angles to be measured were very small, the 0.2 mm distance corresponding to 7.200 sec of arc was taken as the unit of angular measurement. A lead plug 3 mm thick inside the slot cut through *B*₃ prevented high speed electrons from entering the counting chamber.

The counting chamber consisted of a brass cylinder 13 mm in diameter and 5 cm long with a 3 mm aluminum front, cast in the center of the lead block *B*₄ which was insulated from the base and to which the positive high potential connection was made. In especially damp weather dry dust free air was introduced into the chamber before counting. The potential necessary for operating the Geiger counter was supplied by a 3000 volt motor-generator set operating on 100 volts from a storage battery. The output was found to be very steady and constant to within 10 volts.

The electrical counting apparatus was essentially the same as that used by Kovarik.¹⁷ Similar arrangements have been used by others for counting

¹⁷ A. F. Kovarik, Phys. Rev. [2] 13, 273 (1919).

purposes. Fig. 3 is a schematic diagram of the electrical circuit. A loud speaker was used in the output circuit and the sharp clicks heard from it, one for each discharge in the chamber, were counted by a hand tally.

Platinum ball points about 0.003 inch in diameter were found to be very satisfactory. A point was made by melting one end of a half-inch piece of 0.001 inch hard drawn platinum wire in a very tiny gas-oxygen flame. As an indication of their practicability it may be said that throughout the experiments only about eight good points were used, and that with them somewhat more than two million γ -rays were counted.

PROCEDURE

The adjustment of the slit system was accomplished by placing one of the blocks B_2 on the carriage before the other and bringing its slit face into line with the axis of the spectrometer by means of a straight edge. The width of the slit formed by the two blocks was changed by moving the second block and inserting various thicknesses of paper between them, after which the paper was removed.

In general, the experimental procedure was to count the number of γ -ray impulses in a period of 20 minutes for each successive angular position of the slit, in order to obtain a curve of intensity plotted against angular measurement for the whole beam of diffracted rays. The slit system was always moved in the same direction in the course of a series of measurements. In each series a large portion of the spectrum was investigated.

In the preliminary work of measuring the wave-lengths the slit system was realigned several times and adjustments of the slit width and orientation of the crystal were made in order to obtain the best results. The positions D_1 and $-D_2$ of the peaks on either side of the zero were found for a number of wave-lengths. These positions were correlated in pairs and the mean zero of the spectrum determined from the average of $(D_1 - D_2)/2$ for all wave-lengths and used as a basis for further measurements.

The results showed that two diffracted rays could be completely resolved if their angular separation was about 20 sec of arc, corresponding to a difference in their wave-lengths of about 0.6 X.U. Calculation showed however, that for the smallest slit width, 0.126 mm, all the diffracted rays in a beam of at least 5 minutes angular width could pass through the slit and enter the counting chamber. Accordingly, the reasonable assumption was made that the slit must not be in perfect alignment with the image of the source, and in Fig. 1C is shown the manner in which a narrow beam of monochromatic rays from the crystal was assumed to pass through the slit.

Several experiments were performed later which confirmed this view. With the diamond crystal, no peaks could be found when the width of the slit was decreased from 0.126 to 0.063 mm, and also when the width at end 1 was increased to 0.126 again, the width at end 2 remaining 0.063 mm. But when the width at end 2 was made 0.126 and that at end 1 was changed to 0.063 the peaks reappeared. Furthermore, with the calcite crystal and a width of 0.19 mm, the peak at 35 X.U. was found again when the width

at end 1 was reduced to 0.126 mm, but the peak disappeared when end 2 of block *B* was moved the small distance 0.025 mm toward *A*. The position of *A* on the carriage was left unchanged throughout all the experiments. In order to calculate the resolving power, the position of the image of the source with respect to the pivot and the slit system must be known. Assuming their relative positions to be as shown in the figure, the two experiments indicated that two γ -rays could be resolved in the first case if their angular separation was about two minutes of arc and in the second case if the separation was less than one minute.

In the wave-length measurements it was found necessary to use three different slit widths, namely, 0.126, 0.19, and 0.38 mm. For angles of diffraction less than 40 units the first was used in order to have the rate of counting less than 55 per minute. The second was employed to decrease the slope of the background intensity curve for larger angles, and the third was found to be best for angles of diffraction greater than 195 units.

The portion of the background at large angles due to scattered rays was obtained from additional intensity measurements which were made with the slit closed. An intensity curve taken with the crystal removed did not show any peaks proving that they were due to diffracted rays only. A precise determination of the extent to which a possible continuous spectrum raises the background intensity was made by finding the intensities, for the two positions of the crystal, at a particular point on the curve where no peaks were to be expected either for first, second, or third order diffracted rays of any known wave-lengths.

The zero of the transparent scale was compared frequently with the zero of the steel scale and vernier. The deflections on the scale were noted at the beginning and at the end of each 20 minute period. In this way slight variations in the readings which occurred now and then due to the effect of temperature changes in the spectrometer were taken care of.

The operating potential on the Geiger counter was about 1800 volts, the exact value depending on the sensitive point in use. Its magnitude was always adjusted to the potential at which the impulses due to the γ -rays were slightly drawn out. The number of stray counts, or in other words, the number of impulses received when all sources of radiation were removed to a considerable distance, was about two or three per minute. A small test source placed in a definite position with respect to the counting chamber was used in standardizing the action of the points and in testing new ones. One person did the counting in all the experiments.

The expression for the probability of a number of counts n appearing in an interval of time for which x is the true average count was shown by Bateman¹⁸ to be,

$$P = \frac{x^n e^{-x}}{n!}.$$

¹⁸ H. Bateman, Phil. Mag. [6] 20, 704 (1910).

It has also been shown from this that the average deviation from the mean for a number of particles N counted in some interval of time t is $(nt)^{1/2}$, where n is the rate of emission. The probable deviation may therefore be taken as $0.67 (x)^{1/2}$.

Since in the counting experiments there was always the possibility of getting a large deviation at some time or another because of the random nature of the counts, it was the practice immediately to repeat a count

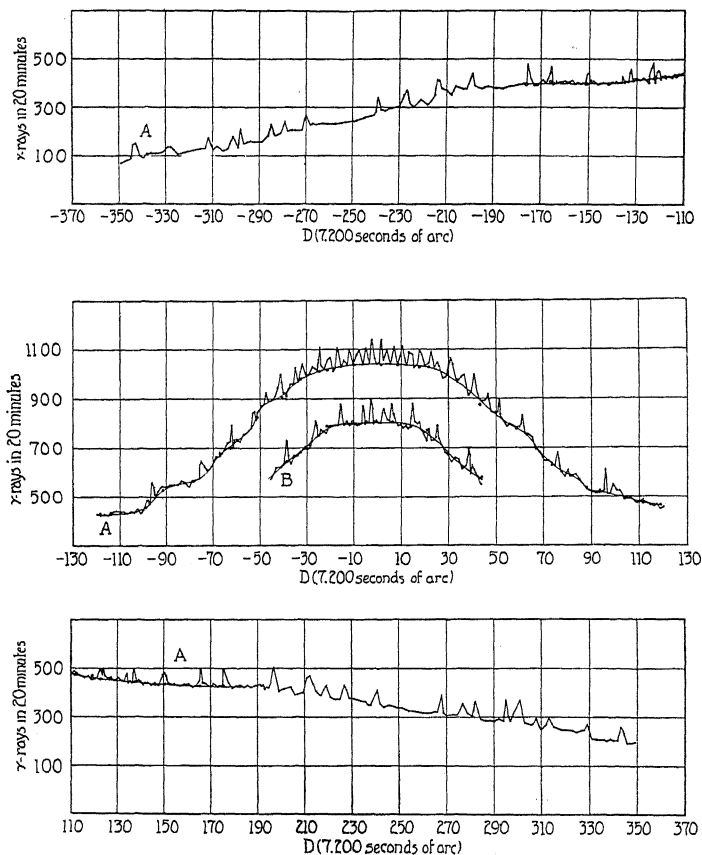

Fig. 4. Gamma-ray spectrum curves. Curve *A* is for the calcite, *B* for the diamond crystal.

which showed a large variation and average it with the other. If there was a true γ -ray intensity maximum or minimum for the position of the slit it was then confirmed, if not, the averaging process served to smooth out or reduce the magnitudes of the large deviations.

RESULTS AND DISCUSSION

The complete intensity curve is shown in Fig. 4 and is presented in three sections on account of its length. The experimental points have been joined by straight lines. Curve *B* was taken with the diamond crystal. The small

circles indicate the intensities obtained for the crystal turned and the base line of the spectrum has been drawn through them. The unit of the abscissa D is 7.200 sec. of arc and corresponds to a wave-length of 0.2115 X.U. for curve A and 0.0618 X.U. for curve B .

The spectrum curve was obtained in five parts, a central portion extending to 45 units and two on either side with overlap. The parts were placed so as to give a continuous curve which was done by changing the ordinates by adding or subtracting a constant quantity. The actual intensity of the background was: 1040 γ -rays in 20 minutes at zero, 420 at 195, and 350 at 340. The intensity of the background for *B* was 1010 at zero, differing slightly from *A* because of a readjustment of the slit width. The large increase in intensity for angles less than 70 was due to γ -rays coming directly from the source. About 15 percent of the general background was made up of scattered rays. Because of the method of procedure in counting, previously described, it is estimated that the experimental error in the determination of the intensity of the background, and the intensities at most of the maximum and minimum points on the curve is about ± 15 γ -ray counts.

It is to be noted that the peaks on the curve are sharp and in general are defined by two or more points. No trouble was experienced in repeating the positions of the peaks and in fact many of the peaks were obtained several times. Taking the expected deviation to be $0.67 (x)^{1/2}$ it is seen that their heights above the background vary from 2 to 7 times the probable deviation depending on the intensity of the background.

The numerical results are given in the Table I. D_1 and $-D_2$ are the positions of corresponding peaks on both sides of the zero of the spectrum. The region of wave-lengths longer than 72.5 X.U. was not completely investigated so that no curves are shown. The values of the γ -ray wave-lengths and their intensities as found by other investigators are also included in the table for the purpose of comparison. The experimental error in the values of λ presented herewith is ± 0.1 X.U. except for wave-lengths longer than 41.8 where it is about ± 0.2 X.U. The four γ -rays of shortest wave-length were also obtained with the diamond crystal. The error in their wave-lengths is ± 0.03 X.U. Ellis-Skinner give an accuracy to their results of one part in 300. Frilley gives an experimental error of ± 0.5 X.U. Consequently there is good agreement among all the results. Many new rays were found and the diamond crystal made it possible to detect the extremely short wave-length of 0.17 X.U. Two additional determinations gave the same value.

The following γ -ray wave-lengths, reported by others for substances certainly present, were not found:

RaB $\lambda = 51.3$ X.U.	Thibaud, $\lambda = 51.5$	Frilley
RaB $\lambda = 47.5$		Ellis-Skinner
RaC $\lambda = 29.5$		Frilley
RaC $\lambda = 23.4$	Thibaud, $\lambda = 24$	Frilley

There is additional information in regard to a few of the wave-lengths, namely:

RaD $\lambda = 265$	Meitner, $\lambda = 264$	Curtiss
RaB $\lambda = 71$	Frilley, possibly 2nd order of $\lambda = 35$	
Ra $\lambda = 66$	Hahn-Meitner	

No particular effort was made to identify higher order diffracted rays and some of those presented in the table may be of that kind.

On account of the complex nature of the radioactive preparation used in the present experiments, it was impossible to tell the exact source of any of the rays. The assignments in the last column, some of which are doubtful, are also from other papers.

The relative intensities of the γ -rays are given in column 5. The height of a peak has been taken as the intensity and a number 10 means that 100 monochromatic rays in addition to the background were counted in 20 minutes. No correction has been made for the fact that three different sizes of slit were used. Some of the peaks were repeated using double the slit width but their heights were found to be increased only about 40 percent. It was therefore considered advisable not to assume any relation between the width of the slit and the intensity of the rays and so attempt to reduce them all to the same basis. On the whole the changes in intensity along the spectrum are in agreement with the results of other observers, but the intensities do not vary as much as in the results of Ellis-Skinner. Although the present method was quite straightforward it is not certain that this disagreement is particularly significant.

It may be seen from Fig. 4 that the base line passes through or a little above the bases of the peaks but not below them as would be the case if there was a continuous spectrum of any appreciable intensity. The more precise measurements made at a wave-length of 53.9 X.U. gave a γ -ray count of 6664 for the crystal set for diffraction through the slit and 6666 in the same length of time for the crystal turned. Since the probable variation in either of these numbers is about ± 0.8 percent, and the smallest peaks on that part of the curve are found to differ from the background by about 9 percent, it would seem that a continuous radiation if existing at all raises the background intensity to less than one-tenth the height of the least prominent peaks here found. Moreover these peaks belong to some of the weakest γ -rays.

It is to be noted that the very short wave-length γ -rays represent a large amount of energy as a wave-length of 1 X.U. corresponds to the energy of an electron after falling through a potential difference of some 12×10^6 volts. The relation between these γ -rays and other high frequency radiations may be inferred from a consideration of the work of Millikan-Cameron¹⁹ and many other investigators. No attempt has been made to correlate the new wave-lengths with the nuclear energy level theories put forward by Ellis²⁰ and others.

In conclusion the author wishes to express his appreciation to Professor A. F. Kovarik for suggesting and directing the work. He is also greatly indebted to Mr. Donald Cooksey for the loan of the diamond.

THE IONIZATION OF CARBON DIOXIDE BY
ELECTRON IMPACTBY H. D. SMYTH AND E. C. G. STUECKELBERG
PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received June 20, 1930)

ABSTRACT

A new mass spectrograph has been constructed entirely of glass except for the electrodes. Furthermore its design reduces thermal dissociation to a minimum. Using this apparatus the products of ionization in carbon dioxide have been studied. The primary ions are found to be CO_2^+ , CO^+ , O^+ and C^+ appearing at 14.4, 20.4, 19.6 and 28.3 volts respectively. There is also some O_2^+ produced as a secondary product with an ionization potential of 20.0 volts. Except for CO_2^+ minimum values for all the ionization potentials can be calculated and are found to agree within the limits of error with the observed values.

THE products of ionization in carbon dioxide as analyzed by a mass spectrograph have already been discussed in a brief note by the authors¹ and in a paper by Kallmann and Rosen.² The present paper constitutes a final report on the authors' work.

The method used was the familiar modification of Dempster's mass spectrograph first used by one of the authors³ in 1922 and since then employed by a number of different investigators. It will not be described in detail particularly as this entire field is to be discussed in a forthcoming article in *Reviews of Modern Physics*. There are, however, a number of minor improvements which should be mentioned.

In the first place the present apparatus is made entirely of glass. The "positive-ray box" which in previous experiments was a rectangular box of brass fitting between the poles of the magnet is now of one inch glass tubing bent in a semicircle and sputtered with platinum to prevent electrostatic charging. One end of this glass "positive-ray box" is sealed to the ionization tube and the other contains the Faraday box which receives the positive ions. This construction eliminates wax joints near the filament and metal parts that cannot be baked out. As a result of it and careful drying of the CO_2 , water vapor ions are negligible except at high pressures.

A second change of design is the use of an electron beam parallel to the magnetic field in order to minimize the bad effects of stray field. Such an arrangement has recently been used by Bleakney.⁴ A diagram of the central part of the present apparatus is given in Fig. 1.

¹ Smyth and Stueckelberg, *Helvetica Physica Acta* **2**, 303 (1929).

² Kallmann and Rosen, *Zeits. f. Physik* **58**, 52 (1929) and *Zeits. f. Physik* **61**, 61 (1930).

³ For references see Gurney and Morse, *Phys. Rev.* **33**, 789 (1929) or Kallmann and Rosen, reference 2.

⁴ Bleakney, *Phys. Rev.* **34**, 157 (1929), **35**, 139 (1930).

Finally and most important an attempt has been made to minimize dissociation by the filament. To do this the apparatus is so arranged that the gas first enters the ionization chamber from which it diffuses toward the pumps through the slits S_1 and S_2 and the circular opening O . Thus there is a continuous flow of gas from the ionization chamber through O past the filament. Unfortunately to get sufficient intensity of ionization the filament has to be very close to O so that there is still a certain amount of thermal dissociation. An attempt was made to get some quantitative estimate of this by thermocouple measurements of the temperature in the ionization chamber but the result was indeterminate. The positive-ray results themselves offer the most definite evidence of dissociation, as will appear below.

EXPERIMENTS AND RESULTS

Carbon dioxide was prepared by fractional distillation of commercial carbonic acid gas. After careful drying over phosphorous pentoxide it was

Fig. 1. Diagram of central part of apparatus.

admitted to the apparatus through traps cooled by CO₂ snow and showed no impurities in positive-ray analysis except a trace of water vapor.

First experiments confirmed what we had already found with the old apparatus and what has also been reported by Kallmann and Rosen, namely, that the ions produced are CO₂⁺, CO⁺, O⁺, C⁺, and O₂⁺. We then proceeded to study these ions in two ways, first by varying the pressure, second by observing critical potentials.

In the pressure runs the field V_1 accelerating the electrons was usually of the order of 40 volts. In both these runs and those on appearance potentials the space OS_1 is, of course, field free, the field V_3 between S_1 and S_2 is of the order of 8 volts and the field V_4 , between S_3 and S_4 , varies according to the mass of the ion according to the equation $(M/e)(V_3 + V_4) = K$ where M is the mass of the ion on the $H^+ = 1$ scale and K for this apparatus and the magnetic field used is about 2600. The pressure used for the most satisfactory of the appearance potential runs was of the order of 0.0008 mm so that the chances of collisions of the second kind or of other secondary effects were small. All the above conditions were varied at one time or another for purposes of control.

Pressure variation. In studying these effects due regard was paid to the recent remarks of Kallmann and Rosen concerning differential absorption

in the magnet space. One of us hopes to discuss this whole problem fully elsewhere, but we may say here that we observed the effect of varying the pressure in the magnet space on the intensities of CO_2^+ , CO^+ , O^+ , and C^+ . The effects were small in the range of pressures we were using and the relative intensities were not appreciably changed except in one case. The one ion which behaved differently from the others was C^+ which had an unusually long free path as might be expected from its low ionization potential.

In Fig. 2 the intensities of the different ions are plotted as functions of p_1 , the pressure in the ionization tube, for a typical set of observations. Two results are striking, the decrease of CO^+ and the increase of O_2^+ at higher

Fig. 2. Intensities of different ions plotted as functions of pressure in ionization tube for a typical set of observations.

pressures. The first is interpreted as the result of collisions of the second kind of the type $\text{CO}^+ + \text{CO}_2 \rightarrow \text{CO}_2^+ + \text{CO}$ which should be possible as the ionization potentials are only one or two tenths of a volt apart. At first sight this seems to contradict the statement above concerning the effect of pressure in the magnet chamber. But we may reconcile the results if we remember that the collision $\text{CO}_2^+ + \text{CO}_2 \rightarrow \text{CO}_2 + \text{CO}_2^+$ may also occur and would reduce the number of CO_2 ions getting through the magnet chamber but not the number of CO_2^+ ions produced in the ionization chamber. Thus collisions of the second kind in the magnet chamber may have little effect on the relative intensities of CO_2^+ and CO^+ but such collisions in the ionization chamber may greatly favor the CO_2^+ . Why the O^+ behaves like the CO_2^+ and CO^+ instead of like the C^+ is not certain. That the C^+ makes few collisions of the second kind is confirmed by its curve in Fig. 2. If that curve

is corrected for the effect of pressure in the magnet space it becomes of the same general type as the CO_2^+ etc. The O_2^+ curve remains as one of entirely different type, a type suggesting strongly a secondary effect. This is supported by the results of Kallmann and Rosen who observed only small traces of O_2^+ . Our final conclusion is therefore that all the ions are primary save O_2^+ .

Ionization potentials. In determining the ionization potential for different ions argon was used as a standard in the following way. Immediately before and immediately after several of the CO_2 runs argon was run into the apparatus and the electron accelerating voltage observed where A^+ ions were just noticeable. This voltage was the same within the limits of error before and after the CO_2 run and was taken as giving the proper correction to the observed value. That this procedure was justified is supported by the agreement between the ionization potential for CO_2^+ thus obtained and the value observed by Mackay.⁵ The ionization potentials for the other ions were then referred to that of CO_2 . A typical set of curves at an intermediate pressure is shown in Fig. 3. At lower pressures the O_2^+ usually can not be

Fig. 3. Typical set of curves at intermediate pressure.

observed but the other curves cut the axis more sharply. The complete weighted results are tabulated below.

From both table and curves we see that CO^+ appears to have two critical potentials. From a comparison of these results with those of an earlier apparatus and from a study of the effect of pressure, filament temperature, etc., we have concluded that the lower potential is due to the presence of CO from thermal dissociation. Whether it may be a true critical potential for CO, to be identified perhaps with Mackay's higher ionization potential at

⁵ Mackay, Phys. Rev. 24, 319 (1924).

* Run shown in Fig. 3.

15.6 volts,⁵ or whether its position depends entirely on the amount of CO present we are not certain. We incline toward the latter view and would explain our previously reported value and that of Kallmann and Rosen in the same way. The higher break, on the other hand, we believe is a true ionization potential due to the direct production of CO⁺ from CO₂.

DISCUSSION

The results given above are particularly interesting because we can compare them with theoretical expectations. We know that carbon dioxide is a straight line molecule with the carbon atom in the middle. It is not surprising therefore that we can get CO₂⁺, CO⁺ and O⁺ all at comparatively low potentials but that to get C⁺ we must break away both oxygen atoms and ionize the remaining carbon so that we require considerably higher energy. Let us be more precise and calculate the minimum values where the different ions might appear. The calculations given in Table II are based on the following values.

Heats of Dissociation ⁶ Process		Volts	Ionizing Potentials ^{7,8,9,10}	
CO ₂ → CO + O		5.7	CO	14.2 ⁷
CO → C + O		10.	O	13.5 ⁸
O ₂ → O + O		5.6	C	11.2 ⁹
			O ₂	13.5 ¹⁰
			A	15.6 ⁹

⁶ Mecke, Zeits. f. Phys. Chem. B7, 108-129 (1930).⁷ Birge, International Critical Tables, Vol. 5.⁸ Frerichs, Phys. Rev. 34, 1239 (1929).⁹ Russell, Astrophys. J. 70, 16 (1929).¹⁰ Stueckelberg, Phys. Rev. 34, 65 (1929).

The probable errors given for the observed values are estimated and based on the assumption that 14.4 for CO₂⁺ is correct. The calculated probable error for $I_o - I_{CO_2^+}$ was only ± 0.074 volts but this is the best determined of the higher ionization potentials.

TABLE II.

Process	Calculated (volts)	Observed (volts)	
		K and R	This paper
CO ₂ →CO ₂ ⁺		14	14.4
CO ₂ →CO ⁺ +O	19.9	18	20.4±0.7
CO ₂ →CO+O ⁺	19.2	17	19.6±.4
CO ₂ →C ⁺ +O+O	26.9	29	28.3±1.5
CO ₂ →(CO ₂ ⁺ +CO ₂)→2CO+O ₂ ⁺	19.3		20.0±1.0

The good agreement between our results and the calculated ones is perhaps somewhat fortuitous considering the uncertainty of some of the heats of dissociation involved as well as the errors in our present experiments. It is difficult to make any comparison with the results of Kallmann and Rosen since they give neither experimental data nor estimated error. Their calculated values differ slightly from ours also, presumably due to use of different authorities for heats of dissociation but here again they do not give the data on which they base their estimates so detailed comparison is impossible.

The value calculated for the production of O₂⁺ postulates an intermediate process, the formation of an excited CO₂⁺ ion. If this is correct it means the CO₂⁺ ion has an energy level, perhaps a metastable one, at 5.6 volts above the normal. We are not yet in a position to judge of the reasonableness of this assumption.

Granting the minor uncertainties discussed in the above paragraphs and earlier it still seems clear that we have more complete knowledge of the effect of electron impact on CO₂ than on any other polyatomic molecule. Moreover it is very striking that the observed ionization potentials agree so closely with those calculated from energy considerations alone since such considerations give minimum values. Previous data, both ionization and thermochemical, on other polyatomic molecules are not so definite. Experiments are now being performed on N₂O and NO₂ molecules for which the heats of dissociation and ionizing potentials of the constituent parts are almost as well known as for CO₂.

THE IONIZATION OF NITROUS OXIDE AND NITROGEN DIOXIDE BY ELECTRON IMPACT

BY E. C. G. STUECKELBERG AND H. D. SMYTH
PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received June 20, 1930)

ABSTRACT

The same apparatus used for the study of CO_2 has now been used to study the products of ionization in NO_2 and N_2O . Thermal dissociation is so serious in NO_2 that the results are somewhat unsatisfactory but NO_2^+ , N^+ and O_2^+ are found as primary ions and their appearance potentials determined approximately. In N_2O the results were more satisfactory and the appearance potentials 12.9, 16.3, 15.3, 21.4 were found for the primary ions N_2O^+ , O^+ , NO^+ , N^+ respectively. In both gases other primary ions were probably present but obscured by ions from products of thermal dissociation. As in CO_2 the observed potentials agreed within the limits of error with calculated values.

PURSUING the general scheme of investigating the simplest triatomic molecules the authors went on from the experiment on carbon dioxide reported in the preceding paper to study the products of ionization in nitrous oxide and nitrogen dioxide. These substances have almost the same advantages as CO_2 as far as our knowledge of their structure is concerned. Not only are the heats of dissociation of the gases themselves known but also the heats of dissociation and ionization potentials of their constituent parts, N_2 , O_2 , NO , N and O . Furthermore both N_2O and NO_2 are supposed to be triangular in structure furnishing an interesting contrast with CO_2 which is linear.

Experimentally, however, difficulties of two sorts arose. The first, which was foreseen, was the high degree of thermal dissociation which made any study of pressure variations futile and all results more difficult of interpretation. The second difficulty was a variable error in the voltage scale which made corrections uncertain and the determination of some of the ionization potentials less accurate than in CO_2 .

EXPERIMENTS AND RESULTS

The apparatus and procedure were the same as those described in the preceding case except that the electrode in front of the filament was changed from nickel to platinum and two fine wires welded across the hole O to make the field more uniform. (see Fig. 1 in previous paper).

The NO_2 was generated by heating $\text{Pb}(\text{NO}_3)_2$ and purified by fractional distillation. In the ionization chamber it was dissociated to such an extent that a typical mass spectrum showed NO^+ ions ten times more numerous than NO_2^+ and showed some N_2^+ and O_2^+ ions present. Therefore the possibility must be considered that the NO^+ , O^+ and N^+ ions observed came from ionization of NO , N_2 or O_2 rather than directly from NO_2 .

The N_2O was generated by heating NH_4NO_3 and was dried over P_2O_5 . The dissociation difficulty appeared here also but with certain differences. In this case the N_2O^+ was the strongest ion with O_2^+ and N_2^+ much stronger

and NO^+ relatively weaker than in the NO_2 mass spectrograms. But again care must be taken in interpreting results though in general they are better than in NO_2 .

Fortunately the resolution of the apparatus was excellent. Therefore it was possible to observe the appearance potentials of nearly all the stronger ions. The only exceptions were N_2^+ and O_2^+ in NO_2 where the great intensity of NO^+ obscured the appearance potentials of the neighboring ions.

Early in the experiments on NO_2 it was noticed that the appearance potential of NO^+ was not as far below that of argon as might be expected. Therefore it was decided to use the ionization potential of mercury as a second calibration point for correction of observed voltages. As may be seen in the tables below, this gave the surprising result that the observed appearance potential of the Hg^+ ion was only about 3.8 volts below that of the A^+ ion instead of the 5.2 which it should be. This is attributed to some variable charged layer or possibly some geometrical effect. Attempts were made to diagnose it more exactly by measuring the velocity and intensity characteristics of electrons reaching probes inserted just behind the hole O , or just above the slit S_1 (see Fig. 1 in previous paper) but the results were inconclusive. However plotting the observed values for A^+ , CO_2^+ and Hg^+ against their true values a correction curve can be drawn and observations of unknown ionization potentials corrected by it. Actually such an interpolation is required in only one case, N_2O^+ . Of the other three ions appearing below 14 volts, NO^+ and NO_2^+ both appear at approximately the same place as Hg^+ while the O_2^+ in the N_2O appears by interpolation at 13.5 which is in agreement with the accepted value of the oxygen ionization potential.

A typical ionization potential curve for N_2O is shown in Fig. 1 and the results of a number of runs on NO_2 and N_2O are tabulated below.

TABLE I.
A. NO_2

Run	P	Hg^+	Observed Ionization Potential				O^+	N^+
			NO_2^+	NO^+	A^+			
2	7×10^{-4}		15.0	14.5	18.2			
3	11		17.5	17.2	20.9			
4	10		17.0	16.5	18.9			
5	9	NO gas		17.5	20.0			
6	10		15.0	15.0	18.5	20.5		
7	10			14.5				
8	12		15.75	15.5	18.5	20.7		23.7

B. N_2O

Run	P	Hg^+	Observed Ionization Potentials (with weights)						O^+	N^+
			N_2O^+	NO^+	A^+	O_2^+	N_2^+			
1	25×10^{-4}		16.5(10)		19.0(10)					
2	18	13.8(10)	15.2(10)		17.3(10)					
3	7	13.6(10)	15.0(10)							
4	12	13.5(10)	15.0(10)		17.5(10)					
5	7		16.1(10)	18.3(10)			18.5(10)	19.7(2)	25.5(2)	
6*	12		16.5(10)	18.3(10)		17.0(10)	18.7(10)	19.5(2)	24.5(2)	
7	12		16.5(10)	17.8(2)	18.5(2)	17.0(10)	18.5(2)			

* Run shown in Fig. 1.

By using argon and mercury as reference points and using the correction curve discussed above we arrive at the following experimental values where

TABLE II

From	NO_2^+	N_2O^+	NO^+	O_2^+	N_2^+	O^+	N^+
NO_2	11.0?		10.5?			17.7?	20.8?
N_2O		12.9	15.3	13.5	15.5	16.3?	21.4

the question marks indicate that the accuracy is poor, perhaps 10% and we refrain deliberately from giving estimated errors for each separate potential. The ones not questioned are probably accurate to about half a volt.

Fig. 1.

DISCUSSION

In comparing these experimental results with theoretical values we must remember that we can safely attribute an ionizing potential to NO_2 or N_2O

TABLE III.

Process	Heats of dissociation	Volts	Ionizing potentials	
	$\text{NO}_2 \rightarrow \text{N} + \text{O}_2$	4.3	N_2	16.5 ²
	$\text{NO}_2 \rightarrow \text{NO} + \text{O}$	3.3	N	14.5 ³
	$\text{N}_2\text{O} \rightarrow \text{N}_2 + \text{O}$	2.0	O_2	13.5 ⁴
	$\text{N}_2\text{O} \rightarrow \text{NO} + \text{N}$	4.6	O	13.5 ^{5,3}
	$\text{NO} \rightarrow \text{N} + \text{O}$	6.5	NO	9.4 ⁶
	$\text{N}_2 \rightarrow \text{N} + \text{N}$	9.1	A	15.6 ³
	$\text{O}_2 \rightarrow \text{O} + \text{O}$	5.6	Hg	10.4 ³

only of the observed value is lower than the theoretical value for production from N_2 , O_2 , or NO . Even the assurance of the chemists that no NO is to

be expected in N_2O must be regarded with skepticism at first though it will be seen later to be verified. With the heats of dissociation given by Mecke¹ and the ionizing potentials from various sources given in Table II the minimum energy can be calculated for fifteen of the seventeen possible processes, which might be expected to occur in NO_2 or N_2O . The two ionization potentials that can not be predicted are, of course, simple ionization of N_2O and NO_2 without any dissociation. Without considering in detail the processes which might lead to each type of ion we may take one as typical. Consider NO^+ . In NO_2 it could be produced directly from NO_2 at 12.7 volts but actually it appears very strongly below this point so that presumably it comes from NO present as the result of dissociation and requiring only 9.5 volts for ionization. On the other hand in N_2O , NO^+ first appears at about 15.3 volts whereas it can first be produced directly from N_2O at 14.0. This suggests that it is actually being produced in this way and that there is no appreciable amount of NO itself present. This confirms the views of the chemists on the nature of dissociation in N_2O and allows us to throw out NO as a possible source of N^+ or O^+ in the experiments on N_2O . The results of arguments of this type are embodied in Table IV below.

TABLE IV.

Process	Theor.	Obs.	Remarks
$NO_2 \rightarrow NO_2^+$		11.0	
$\rightarrow NO^+ + O$	12.7		Obscured by $NO \rightarrow NO^+$
$\rightarrow NO + O^+$	16.8	17.7	Definitely occurs
$\rightarrow N + O_2^+$	17.8		O_2^+ present but I.P. obscured by NO^+
$\rightarrow N^+ + O_2$	18.8	20.8	Uncertain, perhaps due to NO
$N_2O \rightarrow N_2O^+$		12.9	
$\rightarrow N_2 + O^+$	15.5	16.3	Definitely occurs
$\rightarrow N_2^+ + O$	18.5		Obscured by $N_2 \rightarrow N_2^+$
$\rightarrow NO^+ + N$	14.0	15.3	Reasonably certain
$\rightarrow NO + N^+$	19.1	21.4	Reasonably certain

It seems that in every case where a definite conclusion can be drawn it is to the effect that the process to be expected does occur and at nearly the minimum possible energy. Perhaps the most interesting processes are $NO_2 \rightarrow N^+ + O_2$ and $N_2O \rightarrow N_2 + O^+$ which evidently do occur although the corresponding process $CO_2 \rightarrow C^+ + O_2$ does not occur. This is in perfect accord with our ideas as to the difference in structure of these molecules.

These results combined with those on CO_2 give a most satisfactory confirmation of predictions of ionization phenomena by the use of thermochemical data, a process that fell into disrepute after its early failure in the case of HCl . Unfortunately there are few other triatomic molecules for which we have sufficient data to make predictions. However the authors hope to continue the work as well as possible.

THE EFFECT OF INTENSE ELECTRIC FIELDS ON THE PHOTOELECTRIC PROPERTIES OF METALS

BY ERNEST O. LAWRENCE AND LEON B. LINFORD
UNIVERSITY OF CALIFORNIA

(Received June 20, 1930)

ABSTRACT

The photoelectric effect from thin films of potassium and oxygen on tungsten has been studied as a function of strong accelerating fields. Fields as high as 63,000 volts/cm were used which shifted photoelectric thresholds towards the red, the shifts being approximately proportional to the square root of the applied fields. An applied field of 36,000 volts/cm removed the threshold for a pure potassium layer on tungsten from 5620A to 5880A. A film of potassium on a very thick layer of oxygen on tungsten showed a threshold at 6800A which did not vary with applied accelerating fields. However the magnitude of the emission increased with the field suggesting that thick oxygen layers are rough and applied fields over most of such surfaces are much smaller than calculated from the geometry of the electrodes. A layer of potassium on a thin layer of oxygen on tungsten showed a threshold at 7350A for small applied fields which shifted to 7575A for a field of 18,600 volts/cm. A film of potassium on a thinner layer of oxygen—perhaps less than a monatomic layer—exhibited a threshold in small fields at 5830A which was shifted to 5960A by an applied field of 18,600 volts/cm. From the observations of the variations of the shifts with applied fields calculations of the surface fields were made after the manner of Becker and Mueller. It was found that outside the film of potassium on a thin layer of oxygen on tungsten the field followed closely the Schottky image law in the range 1.5×10^{-6} cm to 10^{-5} cm from the surface. The pure potassium film on tungsten exhibited surface fields which were closely image fields between 8×10^{-7} cm and 1.5×10^{-6} cm from the surface but which departed from the image law at greater distances. These observed departures were about equal to the image fields and were much smaller than the surface fields at like distances outside thoriated tungsten filaments as recorded by the thermionic measurements of several observers. The surface fields in excess of the image fields are ascribable to inhomogeneity of the surfaces, regions of different work functions having linear dimensions of the order of magnitude of 10^{-5} cm.

Shifts of photoelectric thresholds by strong accelerating fields are of particular theoretical interest for they involve changes of the work function of a surface without alterations of the other important characteristics of the metal. It is found that the form of the photoelectric sensitivity versus frequency curve remains unchanged over the range of observations and shifts along with the thresholds in intense fields. Thresholds are not sharp but approach the frequency axis tangentially. These observations are in excellent agreement with the theory of the photoelectric effect based on wave mechanics and the Fermi-Dirac distribution of the electrons in metals worked out by Wentzel and modified by Houston.

THE new quantum mechanics in the hands of Pauli, Sommerfeld, Wentzel, Fowler, Houston, Nordheim and others¹ has been highly successful in dealing with many general properties of metals, and has given a particularly satisfactory account of the emission of electrons from metal surfaces.

¹ An excellent résumé of the subject by L. Nordheim is to be found in *Phys. Zeits.* 30, 177 (1929).

The old concept of free electrons in metals has been revived, though to be sure the behavior of these electrons on the present theory differs radically from that of former views. For purposes of discussion of the experimental results herein described it is desirable to emphasize two characteristic features of the new theory.

The first has to do with the work function of a metal surface. The constant b in Richardson's thermionic equation and the photoelectric long wavelength limit have been regarded as measures of the minimum amount of energy given to an electron in the process of its ejection from a metal. On the older theory the free electrons possessed a Maxwellian distribution of velocities and were retained in the metal by a potential difference between outside and inside equal to the work function. The newer theory attributes a Fermi-Dirac distribution of velocities to the electrons and assigns a potential energy barrier at the surface which exceeds the maximum energy of the electrons at the absolute zero of temperature by the amount of the work function. The work function involves more than just the work required to eject an electron from inside to immediately outside a metal, for it includes as well the work required to remove it entirely away from the surface. Outside the metal an electron experiences a force of attraction to the metal produced by its image. In some cases inhomogeneous ion layers also produce electrostatic fields near metal surfaces which aid or oppose the removal of electrons.

It is obviously possible to introduce electric fields at metal surfaces which reduce the image and ion fields, and thereby cause reductions of the work function. Such reductions of the work function in strong fields have been observed by workers in the field of thermionics, and indeed variations of the thermionic emission with applied fields have been used to estimate surface electric fields.

The second feature of the new theory is that it yields a definite probability that an electron will pass into a region in which its classically computed potential energy is greater than its total energy before entering the region. The probability of finding an electron in such a region falls off exponentially with the distance into the region. This feature of the theory is one aspect of the wave nature of matter. It is possible to apply such a strong electric field at the surface of a metal that the potential within a few atom diameters of the surface becomes lower than the energy of some of the electrons within the metal. Any electron, which passes into this region of higher potential far enough to reach the point where the applied field has lowered the potential to that corresponding to the energy of the electron in the metal, will be accelerated away from the surface. This effect, which is analogous to the passage of light unaffected from one glass plate into another when the plates are close enough together, satisfactorily explains the observed emission of electrons in strong fields.

These effects of strong accelerating fields on the emission of electrons from metals, also should be clearly displayed by a dependence of photoelectric emission on such fields. The lowering of the work function by fields

should appear as a shift of the photoelectric threshold to the red, as has been pointed out by Becker and Mueller.² Similarly the ability of electrons to go through high potential barriers should be evidenced in a like manner. That effects of this sort exist, has been indicated by the observation of Ives³ who found difficulty in saturating photoelectric currents from thin alkali metal films, while currents from thicker ones were more easily saturated. Suhrmann⁴ also noted this lack of saturation, and its variation with the thickness of the film, and noted the further effect that the saturation becomes the more difficult the nearer the frequency of the incident light approaches the threshold value. The reports were only qualitative, and no mention was made of a possible shift in the threshold frequency being associated with the phenomena.⁵

Fig. 1. Diagram of apparatus, showing a section through the photoelectric cell with a schematic diagram of the electrical connections. Also *K* a cross-section through the anode *A* on the line *MN*.

The present work was designed to investigate the matter in a quantitative manner with the primary view of verifying the predictions of the newer theories and also to use the experimental data to elicit information on the surface electrostatic forces near various metal surfaces.

APPARATUS AND EXPERIMENTAL METHODS

form of two internally tangent cylinders. In their common wall was a 1 mm slit S , 1 cm long, to allow the light to fall on the tungsten filament F stretched along the axis of the inner cylinder. The filament was held in place by the nickel support D passing through the crescent shaped space between the two cylinders. The screw on cap P and the sliding sleeve Q were so arranged, that when in place they screened all parts of the cathode circuit, inside the tube, from light and external electrical effects. Both filament leads were carried out of the tube so that the filament could be glowed.

The tube was baked out under vacuum for 12 hours at a temperature of 500°C , the metal parts were heated with an induction furnace and the filament glowed at about 2200°C . The potassium was then distilled into the tube after repeated distillations, and the tube was sealed off when the pressure was less than 10^{-6} cm of Hg. To obtain a coating of oxygen on the filament, a little air was allowed into the tube, after baking out and before distilling the potassium, and then pumped out immediately.

Light from a 6 volt, 110 watt ribbon filament lamp, was dispersed by a Van Cittert type double monochromator, which gave light bands about 100 cm^{-1} units wide (corresponding to a width of 32 Å at 5600 Å) which were practically free from stray light. Any desired band of the visible spectrum could be selected by moving the middle slit. This made it unnecessary to change the adjustment of the last slit or of the photoelectric cell when measuring the current for various wave-lengths.

The photoelectric current was measured with a quadrant electrometer E using the accumulation of charge method. To prevent leakage of charge from the anode circuit to the electrometer circuit, a guard ring G consisting of several turns of tungsten wire was placed in the stem carrying the filament leads. Metal foil, used as a screen on the outside of the tube, was also connected to the guard ring circuit. A low voltage battery B_2 and potentiometer R_2 were used to balance out the effects of contact potentials.

The accelerating fields were produced by potentials from a 1500 volt bank of storage "B" batteries B_1 . These were connected across a resistance R_1 of about 5×10^5 ohms. Only a part of the battery potential was applied between the anode and the electrometer case. The remainder was used to produce a negative potential on the compensating condenser C . The ratio of the potentials on the anode and compensating condenser was so adjusted that the electrometer system was rendered immune to fluctuations in the voltage of the batteries.

The data are shown by plotting the sensitivity curves, that is the photoelectric current per unit light intensity against the frequency of the incident light in sec^{-1} units. The absolute values of the light intensity and of the photoelectric current were not determined. The maximum current was of the order of 10^{-14} amps.

The relative intensities of the light of the various wave-lengths were determined by a vacuum thermopile set in the place of the photoelectric cell.

The accelerating fields were calculated from the applied potentials and

the dimensions of the cylinder and filament. The inside diameter of the nickel cylinder was 0.228" or 0.579 cm. The field at the surface of the filament in the cell with a filament 0.9 mil (0.0023 cm) in diameter was $E=160$ V; and at the surface of the filament 3.0 mil (0.0076 cm) in diameter, $E=60.4$ V, where V is the applied voltage.

The small diameters of the filaments together with the fact that only about 0.7 cm of the filament was illuminated explain the small values of the photoelectric currents.

Fig. 2. The photoelectric current as a function of the frequency of the incident light for a potassium film on tungsten for various fields drawing electrons away from the surface. At right, complete curves for three values of the field. At left, similar curves for nine values of the field on an enlarged scale. The fields in volts per centimeter are for the curves A to I: A, 63, 100; B, 36,200; C, 22,100; D, 15,800; E, 9000; F, 3100; G, 1000 H, 260; and I, 0.

EXPERIMENTAL RESULTS

The photoelectric sensitivity curves for a film of potassium on the 0.9 mil tungsten filament, for different voltages are shown in Fig. 2. The three curves to the right are the sensitivity curves over the range of wave-lengths studied. The photoelectric threshold with an accelerating field of 260 volts/

cm, curve *H*, was 5620\AA ($5.35 \times 10^{14} \text{ sec}^{-1}$) and for fields of 36,200 volts/cm, curve *B*, the threshold was shifted to 5880\AA ($5.10 \times 10^{14} \text{ sec}^{-1}$).

At the left, the portions of the curves near the threshold are plotted on an enlarged scale. The scale of frequencies has been doubled and that of the current increased tenfold. The increased scale allows the current taken with

Fig. 3. The photoelectric current as a function of the frequency of the incident light for potassium on a thick layer of oxygen on tungsten. The fields in volts per centimeter for the curves *A* to *C*: *A*, 18,300; *B*, 4570; and *C*, 366.

the nine different accelerating fields to be plotted, while at the right only three representative ones have been selected. The fields for curves *A* to *I* in volts per centimeter are: *A*, 63,100; *B*, 36,200; *C*, 22,100; *D*, 15,800; *E*, 9000; *F*, 3100; *G*, 1000; *H*, 260; and *I*, 0. It was not possible to use higher electric fields, because of the setting in of field currents of the same order of magnitude as the photoelectric currents. *It is evident from the figure that the shift is not proportional to the strength of the field, but as will be shown later,*

is more nearly proportional to the square root of the field. Not only is the threshold shifted, but the entire sensitivity curve is displaced by the field. The curves do not meet the frequency axis at a finite angle, but approach tangentially, as near as can be experimentally determined. The recorded thresholds were arbitrarily chosen as the points where the currents became definitely measurable.

Fig. 4. The photoelectric current as a function of the frequency of the incident light. Curves A and D for the surface of figure 3 after being heated to 1100° C. The fields in volts per centimeter are: A, 18,600; B, 4650; C, 372; D, 0. Curves E to G show data obtained from the same surface after being heated to 1600° C. The fields are: E, 18,600; F, 372; and G, 0.

To test for the existence of contact potentials between the filament and anode, a photoelectric sensitivity curve was made with a retarding potential of 0.7 volts. The curve cut the frequency axis where the frequency was 1.3×10^{14} greater than for zero potential. This corresponds to a shift of 0.54 volts. Thus the contact difference in potential was less than 0.2 volt in a direction to produce an accelerating field.

A layer of oxygen was allowed on the 3.0 mil filament before the potassium was distilled into the tube. The results shown in Fig. 3 show that the thresh-

hold of this surface was not appreciably shifted by fields as large as 18,300 volts/cm. Near the maximum sensitivity, the emission with a field of 18,300 volts/cm was 1.5 times, and at 4570 volts/cm was 1.17 times the emission at 366 volts/cm (curves *A*, *B* and *C* respectively). The oxygen layer shifted the threshold from 5620Å for the pure potassium surface to 7100Å ($4.25 \times 10^{14} \text{ sec}^{-1}$). At the same time the nature of the surface was changed so that the threshold was little affected by the accelerating fields.

The filament was then heat treated at about 600° C for 5 minutes, allowed to cool and observations were made. It was then heat treated at successively higher temperatures up to about 1600° C. Curves *A* to *D*, Fig. 4, show the emission from the filament after being heated to 1100° C and then allowing the potassium to distil back onto the filament with the reduced oxide coating. Heat treating at this temperature produced the first observable difference from the unheated surface. Curves *E* to *G* show the results after the filament had been heated for a few minutes at 1600° C. These curves show only the region near the threshold on the enlarged scale used for the left half of Fig. 2. They are not continued to the frequency axis because when taking the data the region very close to the threshold was not measured in detail. However, single tests made near the threshold showed that for these surfaces these sensitivity curves are tangent to the zero axis.

Of interest is the fact that reducing the thickness of the oxygen film shifted the threshold still farther to the red, that is to 7500Å ($4.0 \times 10^{14} \text{ sec}^{-1}$), and then the further removal of the film shifted the threshold back to 5880Å ($5.1 \times 10^{14} \text{ sec}^{-1}$) or nearly back to the value found in the first cell.

The maximum photoelectric emission per unit light intensity of the surface with a thick oxygen layer and that of the same surface after being heated to 1100° C was about one-seventh that of the surface after most of the oxygen had been removed by heating to 1600° C. This latter surface had a photoelectric emissivity about equal to that of the pure potassium film on tungsten.

Throughout the investigation it was noted that after heating the filament, and thereby removing the potassium and some of the oxygen, from 24 to 48 hours elapsed before the characteristics of the surface became constant.

DISCUSSION OF RESULTS

Evaluation of surface fields from experimental data.

As previously stated, a considerable portion of the work function of metal surfaces can be accounted for by assuming that the field through which an electron leaves the surface is that due to its own image in the metal. This was considered by Lennard⁶ and Debye⁷ and discussed in detail by Schottky.⁸ If an electron is at a distance x from the surface, its image produces a field E_i of magnitude,

⁶ P. Lennard, Ann. d. Physik 8, 149 (1902).

⁷ P. Debye, Ann. d. Physik 33, 441 (1910).

⁸ W. Schottky, Phys. Zeits. 15, 872 (1914).

$$E_i = -\frac{e}{(2x)^2} = -\frac{e}{4x^2}. \quad (1)$$

The potential of the image field at the distance x from the surface, considering the zero potential to be at $x = \infty$ with no accelerating field, would be:

$$V_i = -\int_{\infty}^x E_i dx = -\int_{\infty}^x \frac{e dx}{4x^2} = -\frac{e}{4x}. \quad (2)$$

Now if an external accelerating field E_a be applied, its potential at a distance x from the surface would be:

$$V_a = -E_a x \quad (3)$$

and the potential resulting from the two fields, the sum:

$$V = -\frac{e}{4x} - E_a x. \quad (4)$$

To find the maximum potential, the derivative of Eq. (4) may be equated to zero which is the same as equating the resultant field to zero.

$$-\frac{dV}{dx} = E = -\frac{e}{4x^2} + E_a = 0. \quad (5)$$

Solving for the value of x at the maximum:

$$x_{\max} = \frac{1}{2} \left(\frac{e}{E_a} \right)^{1/2}. \quad (6)$$

Substituting this value in (4) gives the value of the maximum potential:

$$V_{\max} = -\frac{e}{4} 2 \left(\frac{E_a}{e} \right)^{1/2} - \frac{E_a}{2} \left(\frac{e}{E_a} \right)^{1/2} = -(eE_a)^{1/2}. \quad (7)$$

Since the potential of the free electron has been chosen as zero, $(eE_a)^{1/2}$ represents the reduction in the maximum of the potential energy curve due to the applied field E_a . If the image forces were the only ones acting on an electron leaving the surface, this reduction in potential would represent the reduction of the work function of the surface.

This simple explanation will not hold for all distances from the surface, since the integral in Eq. (2) becomes infinite for $x=0$, which would represent an infinite work function. However of course for distances of atomic magnitude from the metal, the image forces no longer are of this form. The precise manner in which the field departs from the ideal image law is of no consequence to the present discussion.

Regardless of the assumed law of force near the surface of the emitting metal, an increase in the strength of the accelerating field will reduce the work function of the surface. When an electron is leaving the surface of a metal under the combined action of the surface fields and an accelerating field, it is

retarded until it reaches a distance from the surface x_1 where the applied field equals the surface field. As soon as it passes that point it is free and is accelerated from the surface. If the accelerating field is increased by an amount ΔE_a in es units, the field which the electrons must overcome is reduced by an equal amount, and since the electrons must work against this field for a distance x_1 to escape, the decrease in energy necessary for unit charge to escape would be:

$$-\Delta\chi = x_1\Delta E_a. \quad (8)$$

Where $\Delta\chi$ is the change in the work function due to the change in the applied field ΔE_a . Dividing Eq. (8) by ΔE_a and considering the limit as ΔE_a approaches zero:

$$\frac{d\chi}{dE_a} = -x_1. \quad (9)$$

Thus observations on changes of the work function in strong fields yield directly the magnitudes of the electric fields near the surfaces. This method of evaluation of surface fields is due to Becker and Mueller.⁹

The above holds for any kind of electron emission, and the photoelectric threshold frequency gives a convenient measure of the work function as given by the Einstein relation:

$$h\nu_0 = e\chi. \quad (10)$$

Differentiating Eq. (10) and solving for $d\chi$ one obtains

$$d\chi = \frac{h d\nu_0}{e}. \quad (11)$$

Substituting the value of $d\chi$ from (11) into (9)

$$\frac{d\nu_0}{dE_a} = \frac{x_1 e}{h}. \quad (12)$$

Or expressing the field E_v in volts per centimeter:

$$\frac{d\nu_0}{dE_v} = -\frac{x_1 e}{300h} \text{ or } x_1 = -\frac{300h}{e} \frac{d\nu_0}{dE_v}. \quad (13)$$

Thus the distance from the surface x_1 where the applied field equals the surface field, is proportional to the slope of the ν_0 vs. E_v curve, evaluated at the particular value of the field in question.

This method of determination of the surface fields is independent of an exact measurement of the threshold, and depends only on the measurement of the displacements of the threshold. These displacements were measured a short distance away from the zero current axis, where the slopes of the curves were greater and the accuracy of the current measurements better.

⁹ See ref. 2.

This procedure was justified because the electric fields produced a parallel displacement of the curves. The shifts could thus be determined with considerable accuracy.

In Fig. 5 curve *A* shows the Schottky shift as calculated from Eq. (7) making allowance for the change in units. Curve *C* shows the shift of the threshold of the pure potassium surface from the data of Fig. 2. The sur-

Fig. 5. Curves *A* to *C* show the shift of the threshold as a function of the field. Curve *A* the Schottky shift; *C*, the shift for the pure potassium surface; *B*, the shift for the surface heated to 1600° C, and the black dots the shifts for the surface heated to 1100° C. The curves *D* show the fields near the surface as a function of the distance from the surface. The type of line indicates the curve *A* to *C* from which it was deduced.

face with a thick oxygen layer showed negligible shift and was not plotted. The shifts measured from the curves *A* to *D* Fig. 4 were so nearly the Schottky values that the displacements are shown by the black dots only. This was the surface produced by heat treatment at 1100° C. Curve *B* shows the displacements measured from curves *E* to *G* Fig. 4, and shows the displacements of the threshold of the surface after being heated to 1600° C. From the three curves only two displacements could be measured, but

since both of these fell about midway between the theoretical curve and curve *C*, it was assumed that the complete curve was about as drawn.

The curves marked *D* show the fields calculated from the slope of the experimental curves *B* and *C* as compared with a calculated image field, drawn as a solid line. The single circles above fields of 20,000 volts/cm show the fields calculated from curve *C*. They show that the fields are very closely image fields between 7×10^{-7} and 1.2×10^{-8} cm from the surface. At greater distances, the fields of the two surfaces are greater than image fields. The field near the surface after it was heated to 1100°C is about the image field, and apparently the surface with a thick layer of oxygen under the potassium had only negligible fields which could be overcome by the applied fields.

It is of interest to note how closely the observed surface fields coincide with the image field within 1.2×10^{-6} cm of the surface. The deviation at greater distances is undoubtedly real though small. It is very small compared to the large deviations noted by Becker and Mueller,¹⁰ Reynolds¹¹ and others for thoriated tungsten surfaces.

The possible sources of fields greater than the Schottky fields at large distances from the surface have been discussed by many investigators.¹² The best explanation seems to be that the potassium film is not uniform over the surface, so that there are areas of different work functions. The areas of lower work function are electropositive with respect to those of higher work function. The electrostatic fields between these areas are in such a direction as to retard electrons leaving the surface through areas of lower work function. Near the threshold frequency, only the areas of lower work function are able to emit, and these electrons emerge with a retarding field equal to that of their image plus that due to the potential differences on the surfaces. The image field falls off as the square of the distance from the surface, while the fields due to these patches fall off much more slowly. Over the center of such a patch the field would be essentially constant to a distance comparable with about one-tenth of the diameter of the patch. Thus the extra field might be negligible compared to the image field near the surface and at greater distances become larger than the image field. It should be emphasized that to account for the deviation from Schottky fields at distances of 5×10^{-6} cm from these surfaces, it is necessary to postulate the existence of patches having a diameter about ten times this magnitude. Irregularities of atomic dimensions such as unequal distributions of ions over the surface as has been proposed by Suhrmann¹³ are not capable of accounting for the experimental facts.

Since the film of potassium on the layer of oxygen which removed the

¹³ R. Suhrmann, *Naturwissenschaften* **16**, 616 (1928).

threshold farthest to the red exhibited very closely the Schottky field, it follows on this view that such films are homogeneous, and free from patches. In other words, the ions are distributed uniformly over the surface. Moreover it follows that the alkali film surfaces of the present experiments were much more homogeneous than the surfaces of thoriated tungsten studied by Becker and Mueller, Reynolds and others.

It is not evident why the surface with a thick oxygen layer should fail to show a reduction in the work function when the accelerating field is applied. There are two possible explanations. One is that the ions are about 300 atom diameters out from the surface of the tungsten, and the field between the positive potassium layer and the tungsten counteracts the image field in this region. At distances farther out, the image field is small and the counteraction of this by the applied field would not shift the threshold appreciably. The other postulates that the thick oxide layer is extremely rough, and the applied field can lower the work function of only the highest points, and since these constitute only a small part of the area, their emission would not appreciably affect the observed threshold. The principal part of the emission would occur from the hollows where the externally applied fields would be always greatly reduced. The small increase in the field would greatly assist the electrons emitted in the cavities to emerge without striking the walls of the cavity. This latter explanation seems to be more probable since this surface showed much poorer saturation than any of the others.

Comparison with theories of the photoelectric effect.

For the several surfaces and the many surfaces fields, i.e. the many thresholds studied in the present experiments the shape of the photoelectric sensitivity curves remained the same. Thus the form of the curve is practically independent of such superficial factors as the form of potential barriers at metal surfaces and therefore is of interest theoretically as well as experimentally.

From the standpoint of the wave mechanics, Wentzel¹⁴ has calculated the rate at which free electrons in a metal are excited to higher energy states which enable them to escape over the potential wall of a metal surface, when light falls on that surface. He finds that this rate Z for light of frequency ν having electric vectors proportional to E_x , E_y , E_z incident on a metal surface with the normal along the x direction is:

$$Z \sim \frac{1}{\nu^{7/2}} \xi^2 \left\{ E_x^2 + \frac{m}{2h\nu} \left[\frac{1}{2} \xi^2 E_x^2 + \eta^2 E_y^2 + \zeta^2 E_z^2 \right] \dots \right\} \quad (14)$$

where ξ , η , ζ are the velocity components of the electrons before the excitation by the light. He derived an expression for the total photoelectric emission from a surface by integrating the above expression over the distribution of energies of the electrons in the metal. In order to obtain approximate

¹⁴ G. Wentzel, in Sommerfeld's 60. Geburtstag Festschrift, Probleme der Modernen Physik, edited by P. Debye, p. 79. Leipzig, 1928.

expressions he assumed the distribution of energies to be the Fermi-Dirac distribution at the absolute zero of temperature—a distribution of the form:

$$n(\epsilon)d\epsilon = 4\pi \left(\frac{2m}{h^2} \right)^{3/2} \frac{(\epsilon)^{1/2} d\epsilon}{e^{(\epsilon-\bar{\epsilon})/kT} + 1} \quad (15)$$

where $n(\epsilon)d\epsilon$ is the number of electrons having energies between ϵ and $\epsilon+d\epsilon$. It is seen that at absolute zero the number increases as the square root of ϵ to a sharp upper limit for $\epsilon=\bar{\epsilon}$, the maximum energy of the Fermi distribution above which no electrons exist. The expression for the probability of excitation of an electron in the metal by impinging light indicates that the probability varies approximately as the square of the velocity of the electron and as the frequency of the light to the inverse 7/2 power. The Fermi distribution clearly led then to a formula for the total emission as a function of the frequency, having a sharp rise from a threshold value corresponding to the minimum energy necessary for an electron, having the maximum energy $\bar{\epsilon}$ of the Fermi distribution, to escape from the surface. The formula obtained in the case $\nu_0 < \nu < \nu_a$ is the following:

$$I \sim [\bar{\nu}^{5/2} - (\nu_a - \nu)^{5/2}] \nu^{-7/2} E_x^2 + \frac{1}{14} [\bar{\nu}^{7/2} - (\nu_a - \nu)^{7/2}] \nu^{-9/2} [3E_x^2 + 2E_z^2 + 2E_y^2] + \dots \quad (16)$$

Where $h\bar{\nu} = \epsilon$, the maximum energy of the Fermi distribution at 0°K, $h\nu_a = \epsilon_a$, the energy required by an electron at rest in the metal to escape over the potential barrier, and $\nu_0 = \nu_a - \bar{\nu}$ is the threshold frequency. For $\nu < \nu_0$ there is no emission, and for $\nu > \nu_a$, $I \sim \nu^{-7/2}$. The maximum of the photoelectric sensitivity curve is in the interval $\nu_0 < \nu < \nu_a$, and this comprises the frequencies used in the present research.

The above expression really gives the rate at which electrons in the metal acquire enough energy to emerge from the metal and of course is equal to the photoelectric emission provided that the excited electrons do not make an appreciable number of inelastic impacts before striking the surface of the metal normally. Houston¹⁵ has pointed out this tacit assumption of electron elastic impacts in Wentzel's derivation and believes a more nearly correct estimate of the photoemission would take account only of the electrons having great enough energies in their velocity components normal to the surface to escape. Integrating then the expression over the distribution of velocities normal to the surface in excess of a minimum value requisite to overcome the potential barrier, Houston has obtained the following expression:

$$I \sim \left(\frac{\bar{\epsilon}}{h\nu} \right)^{1/2} \left\{ \frac{E_x^2}{\nu} \left[1 + \frac{\bar{\epsilon}}{2h\nu} \right] + \frac{E_y^2 + E_z^2}{3\nu} \left[\frac{\nu - \nu_0}{\nu} \right] \right\} \left(\frac{\nu - \nu_0}{\nu} \right)^2 \quad (17)$$

where I is the photoelectric emission at 0°K, $\bar{\epsilon}$ corresponds to the maximum

¹⁵ We wish to thank Professor W. V. Houston for allowing us to read an unpublished manuscript dealing with this point.

energy of the electrons in the degenerate Fermi distribution and ν_0 is the threshold frequency.

Wentzel¹⁶ is in agreement with Houston on the necessity of taking account of the distribution in direction of the velocities of the electrons in the metal in computing the rate of emission and has modified his original expression (16) obtaining

$$I \sim 1/\nu^{7/2} \left\{ \frac{1}{3} \bar{\nu} [\bar{\nu}^{3/2} - (\nu_a - \nu)^{3/2}] - \frac{1}{5} [\bar{\nu}^{5/2} - (\nu_a - \nu)^{5/2}] \right\} E_x^2 \quad (18)$$

+ higher powers in $\bar{\nu}/\nu$ (for $T=0^\circ\text{K}$) which is essentially the same as Houston's formula in so far as the first term of the expansion in $\bar{\nu}/\nu$ is accurate.

It has been thought by some that photoelectric thresholds are sharp, and thus in accordance with Wentzel's formula¹⁶ and that lack of sharpness is ascribable to experimental errors, such as those introduced by scattered light. Others have observed photoelectric sensitivity curves approaching the frequency axis with zero slope, as is the case in the present experiments.¹⁷ A simple calculation shows that the rounding off introduced by the temperature effects accounts for about half of the observed lack of sharpness of the thresholds in the present experiments, if Wentzel's first method of calculation be assumed. *Houston's calculation (Eq. (17)) corrected for temperature effects is adequate to account for nearly the whole tailing off of the here recorded sensitivity curves.* In a later experiment it is hoped to verify the calculated magnitude of the temperature effect by studying the sensitivity as a function of the temperature.

Fowler¹⁸ has discussed the sharpness of photoelectric thresholds in a manner similar to Wentzel's original deduction, and therefore Houston's objections apply equally well to Fowler's conclusions that thresholds are sometimes sharp.

It has been mentioned that electrons can pass through regions of potential greater than that corresponding to their energy. The magnitude of the effect of applied fields at a metal surface is contained in the following formula:¹⁹

$$D(W) = \frac{4[W(W - \epsilon_a)]^{1/2}}{\epsilon_a} e^{-4\kappa(\epsilon_a - W)^{3/2}/3Ee}, \quad \kappa^2 = \frac{8\pi^2 m}{h^2} \quad (19)$$

where $D(W)$ is the probability that an electron with an energy W for the component of its velocity normal to the surface, will pass through a potential barrier whose maximum is ϵ_a volts greater than the zero of energy in the metal, when an accelerating field E is applied. For the maximum field, 63,000 volts/cm, used in the present experiments and assuming ϵ_a to be 7 volts, the probability $D(W)$ that an electron whose kinetic energy W is nor-

¹⁶ We wish to thank Professor Wentzel for this information sent to us in a private communication.

¹⁹ See ref. 1.

mal to the surface is 0.1 volt less than ϵ_a , the amount required to go over the potential barrier, is less than 10^{-15} . It is evident therefore that this type of influence of the shape of the photosensitivity curve was inappreciable for the fields used in the present experiments. A more favorable case for the observation of this influence of strong fields on photoelectric emission would be that of a metal having a high work function like pure tungsten where much higher electric fields may be applied before the autoelectronic current becomes appreciable.

The changes of the whole photoelectric sensitivity curves produced by applied accelerating fields observed in the present experiments are of fundamental interest, for the effect of the applied fields is to alter the work function without affecting any other characteristics of a metal concerned in its photoelectric properties. Both Wentzel's and Houston's formulas agree in indicating that over the present range of observation the whole photoelectric sensitivity curve shifts by approximate parallel displacement along the frequency axis with the threshold. Alteration of the nature of the work function (the surface electrostatic fields) does not affect markedly the form of the sensitivity curve. *This prediction of the wave mechanical theory of the photoelectric effect is strikingly confirmed in the present experiments.*

THE MAGNETIC ISOTROPY OF COPPER CRYSTALS*

BY CAROL G. MONTGOMERY

SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received June 23, 1930)

ABSTRACT

The variation in the magnetic susceptibility with the direction of the applied field was investigated for large single crystals of copper. A modification of Curie's method of measurement was used. A Fourier analysis of the results indicates that there is no variation of susceptibility larger than 1%, a result consistent with the magnetic isotropy of cubic crystals predicted by the theory of W. Thomson.

I. INTRODUCTION

SINCE its conception in 1851, the description by means of the familiar ellipsoid of magnetization of the variation of the magnetic susceptibility of a non-ferromagnetic crystal with respect to the direction of the applied magnetic field has been accepted as correct until quite recently. It follows from this theory that for substances which form cubic crystals, there can be no dependence of the magnetic susceptibility upon direction of applied field so that the material must be magnetically isotropic.

In 1926, J. Forrest¹ performed some qualitative experiments on a number of cubic crystals and found that they were not isotropic, but that they showed variations in susceptibility as do single crystals of iron and nickel. McLennan and Cohen² investigated the magnetic susceptibility of large single crystals of a number of metals, and found that while bismuth seems to follow a law of variation with the direction of the magnetic field in accord with the accepted theory, antimony deviates noticeably from it. In addition, recent work³ on the Peltier and Thomson effects, which should obey the same symmetry relations as the magnetic susceptibility, seem also to show a deviation from the theory. Thus the accepted theory may have a more limited range of application than hitherto supposed, and it was deemed advisable to reinvestigate a cubic crystal, and to determine whether or not it is magnetically isotropic.

II. APPARATUS AND METHOD OF MEASUREMENT

In order to measure the susceptibilities of crystals it was decided to use a modification of Curie's method which has been developed to quite an extent by P. Weiss and his collaborators, a description of the final apparatus

being given by Foex and Forrer.⁴ The apparatus described below differs from theirs in several details.

A beam, 90 centimeters long, composed of three parallel lengths of quarter inch balsa wood, fastened at the ends and in the center at the corners of equilateral triangles, is suspended by five silk threads approximately 50 centimeters in length. These five suspensions are arranged so as to permit translation of the beam only in the direction of its length. They are hung at the top from a heavy iron frame in such a way that their lengths can be separately adjusted. The lower member of the beam is extended at one end and carries a small piece of aluminum with a vertical hole drilled in it about 2 centimeters deep. Into this hole fits the shaft of a crystal holder on which the crystal is placed. The crystal holder consists of a 7 centimeter length of #16 sterling silver wire on which fits a small cylindrical cap of amber, cut away at the top to fit the crystals, and graduated on the side every 10°. These graduations could be observed by means of a reading microscope and the azimuth of the holder thus read off. An electromagnet capable of producing fields up to about 5000 gauss was used. It was equipped with special pole pieces so as to obtain a field which has a high value of the product of the field by its derivative over a large area. Under the crystal holder, a small saddle, constructed out of copper wire and a small piece of paper, was fastened. This could hold either the crystals or the standard on the beam but was out of the field while measurements were being taken.

The other end of the balsa wood beam carried a celluloid cylinder 6 centimeters in diameter and 15 centimeters long, closed at one end, into which fits a piece of wood with a clearance all around of about 4 millimeters. This provides air damping which, combined with the electromagnetic damping of the sample in the field, is quite satisfactory.

At the center of the beam and perpendicular to it, is an aluminum arm extending some 10 centimeters out, to which is firmly waxed a phonograph needle pointing in the direction of the beam. This needle rests against and perpendicular to a microscope cover glass 1 centimeter in diameter. This is attached to the back of a galvanometer mirror suspended at both ends by a tightly stretched vertical quartz fiber of diameter about 50 microns. The plane of the cover glass makes an angle of 135° with the mirror. Light from an illuminated cross hair is reflected by the mirror and falls on a scale some two meters distant. Thus this arrangement acts as an optical lever and gives a total magnification of the motion of the beam of about 1000 times. The whole arrangement was placed in a wooden box having a large glass window on the side in order to stop air currents. The box was put on a stone pier in a sub-basement room to avoid mechanical vibrations.

When current is passed through the magnet coils, a force is exerted on the specimen and the beam will deflect until the force of gravity balances out the magnetic force. Suppose to do this the beam moves a distance x , and let l be the effective length of the suspensions, m the total mass of the suspended system, f the magnetic force, and g the acceleration of gravity.

⁴ G. Foex and R. Forrer, *Jour. de Physique* [6] 7, 180-187 (1926).

Then

$$x = fl/mg \quad \text{when } x \ll l.$$

Now if the crystal has a susceptibility* k in the direction of the field, we have

$$f = \int k H_y \frac{\partial H_y}{\partial x} dv$$

where the x -axis is in the direction of the beam, the y -axis in the direction of the field, and the integral is taken over the volume of the crystal. Now if the variation of f with respect to x is small, then

$$x = Ak$$

where A is a constant. Hence, if we have a substance with a known value of the susceptibility, we can measure the susceptibility of any other substance by determining the value of A .

In order to test the validity of the assumption that f does not vary appreciably with the position of the crystal, a series of values of x were measured for various values of the field strength. We see from the above equations that

$$x \sim H_y \frac{\partial H_y}{\partial x} \sim H^2$$

if the assumption is justified, and hence if we plot values of x as a function of H^2 we should get a straight line through the origin. With values of the field strength measured in arbitrary units by a ballistic method, we find that within the limits of accuracy of a reading, we do get such a straight line.

Measurements were made of the variation of susceptibility of single crystals of copper as a function of the azimuth of the field. Gold was used as the standard substance. We see that to compare susceptibilities of two substances by this method we must keep the mass of the beam constant. Hence the following procedure was followed in measurement. The gold standard was placed in the paper saddle, and a copper crystal in the crystal holder. Then a series of deflections of the spot of light was observed for 36 azimuths of the crystal. Then the crystal was removed and placed in the saddle, while the gold was placed in the holder. A series of deflections for four azimuths was then taken. Then both the crystal and the gold were placed in the saddle and the deflections due to the holder alone were observed for the same four azimuths.

The zero shift over the whole period of time required for one such set (about ten hours) was not more than 50 to 75 millimeters.

III. PREPARATION OF SPECIMENS AND DETERMINATION OF THEIR ORIENTATION

The copper crystals used in these experiments were obtained from the Hammond Metallurgical Laboratory, Yale University, through the courtesy

* This is not a true susceptibility, but the difference between the susceptibility of the crystal and the surrounding medium, in this case, air.

of Dr. C. H. Mathewson. They were prepared⁵ from the highest purity electrolytic copper by slowly lowering a graphite crucible containing the molten copper out of an induction furnace whose temperature at the center was maintained well above the melting point of copper. The rate of lowering was about 0.6 centimeter per hour. The single crystals so obtained were in the form of rough cylinders approximately a centimeter in diameter and 12 to 15 centimeters long. When these rods were etched in a 50 percent solution of nitric acid for a short time, and then washed, the surface of the rod would shine out brilliantly when held at certain positions with respect to parallel incident light. This is due to the fact that the etching process forms micro-

Fig. 1. Stereographic projection of the axes of the crystal rod.

scopic pits in the surface whose sides are definite crystal planes, and it is the light reflected from these pit-faces that gives rise to the selective reflection. It is evident that if the positions of these faces with respect to the rod as a whole could be determined, and the crystallographic form of these faces identified then the orientation of the crystal lattice with respect to the rod as a whole could be obtained. Bridgman⁶ has described one method of accomplishing this, but a more convenient, if not more accurate, arrangement was used here. The lenses were all removed from the telescope tube of a large polarizing spectrometer, and a plane piece of glass was fastened to the end of the telescope so that the normal to its plane was horizontal and made an angle of 45° with the axis of the telescope. The crystal rod was mounted horizontally and attached to a vertical circle carried by the

⁵ C. H. Mathewson and K. Van Horn, A. I. M. E. Tech. Pub. No. 301-E-109, Feb., 1930.

⁶ P. W. Bridgman, Proc. Amer. Acad. 60, 305-383 (1925).

collimator tube. The light of a small carbon arc with condensing lenses was thrown on the piece of glass on the telescope and reflected to the crystal. By changing the position of the crystal with respect to the light beam, it could be adjusted so that the light from a reflecting surface could be viewed through the telescope. The spherical coordinates of the normal to the pit-face could then be read off the horizontal and vertical circles. The points corresponding to these coordinates were then drawn on a 15 centimeter marble sphere, and the crystallographic planes corresponding to each reflection maximum could be identified. The position of the rod axis with respect to the crystal lattice was then determined by plotting the observed angles on a stereographic net.

Considerable difficulty was sometimes experienced in getting reflections which could be unambiguously identified. The etching process seems to be a difficult one to control satisfactorily, a condition due to the fact that the reaction is a complicated one and particularly dependent upon the amounts of the end-products present in the etching solution. Various concentrations of nitric acid were tried, and consistent results were obtained more often with a 50 percent by volume solution than with any other. Figure 1 shows the stereographic projection of the rod axes of the crystals used.

The specimens were prepared by cutting off a section from the long rod. In order to cut the single crystal rods without spoiling them by introducing too large strains, the following method was used. Two vises were set up and the jaws accurately aligned on the bench of a milling machine. The rod was well padded with paper and held firmly in one vise between two V-blocks. In the other vise was held a jig consisting of two guide slots attached to a piece of steel at right angles to its length. A hack saw blade, 0.025 inch (0.064 centimeter) thick, with all the set removed from the teeth, fitted into these two slots and could be moved only in the plane defined by them. From 30 to 40 minutes were taken to make a cut, and plenty of oil was used. When a section had been cut off, the burr was removed with a fine file and the surface removed in a 50 percent nitric acid solution until the characteristic shine was restored. Care had to be taken to keep the crystals away from moist air, as they tarnished quite rapidly.

The following table gives the dimensions of the crystals used.

Crystal	Diameter	Length	Mass
II	0.764 cm	0.991 cm	3.921 gram
III	0.767	0.968	3.849
IV	0.770	0.993	4.057
VII	0.772	0.942	3.927
Gold Standard	0.770	0.975	8.752

As a substance of standard susceptibility, a piece of gold was used. It was obtained from Baker and Co. who stated that the purity was over 99.99 percent. A piece was machined out whose size was close to that of the crystal specimens. The value of the susceptibility chosen was that obtained

by Owen,⁷ viz., -0.141×10^{-6} cgs. This same value was obtained by Seeman and Vogt,⁸ who have recently investigated copper-gold alloys.

No traces of ferromagnetic impurity could be detected in either the copper crystals or the gold standard.

IV. REDUCTION OF OBSERVATIONS AND RESULTS

In order to insure that the copper crystals used were sufficiently representative, average values of the susceptibility were obtained for each. Taking into account small corrections due to the magnetic effect of the crystal holder and of the air, we get the following values of the specific susceptibility of the different crystals:—

Crystal	$\chi_{\text{Cu}} \cdot 10^6$
II	-0.088
III	-0.075
IV	-0.086
VII	-0.091
Mean	-0.085

The spread of values here is just about that to be expected. Owen⁷ gives the value

$$\chi_{\text{Cu}} = -0.085 \cdot 10^{-6}.$$

In order to bring out any possible anisotropy in the susceptibility of copper it is sufficient to use relative values of the susceptibility only. The values of the deflections obtained with a crystal in the holder were therefore subjected to a Fourier analysis, obtaining the coefficients of the first four cosine and the first four sine terms.

We obtain the following results in millimeters.

$$\begin{aligned} x_{\text{Cu II}} = & 76.31 - 1.88 \cos \varphi - 0.68 \cos 2\varphi - 0.36 \cos 3\varphi \\ & + 0.30 \cos 4\varphi - 0.68 \sin \varphi - 0.44 \sin 2\varphi \\ & + 0.11 \sin 3\varphi - 0.61 \sin 4\varphi, \end{aligned}$$

$$\begin{aligned} x_{\text{Cu III}} = & 68.85 - 2.41 \cos \varphi - 0.36 \cos 2\varphi + 0.08 \cos 3\varphi \\ & - 0.05 \cos 4\varphi - 0.39 \sin \varphi - 0.16 \sin 2\varphi \\ & - 0.07 \sin 3\varphi - 0.05 \sin 4\varphi, \end{aligned}$$

$$\begin{aligned} x_{\text{Cu IV}} = & 75.88 - 0.95 \cos \varphi - 0.29 \cos 2\varphi + 0.16 \cos 3\varphi \\ & - 0.03 \cos 4\varphi - 0.45 \sin \varphi + 0.36 \sin 2\varphi \\ & + 0.15 \sin 3\varphi + 0.03 \sin 4\varphi, \end{aligned}$$

$$\begin{aligned} x_{\text{Cu VII}} = & 76.30 - 0.87 \cos \varphi - 0.26 \cos 2\varphi + 0.38 \cos 3\varphi \\ & + 0.02 \cos 4\varphi + 0.24 \sin \varphi + 0.41 \sin 2\varphi \\ & + 0.01 \sin 3\varphi + 0.00 \sin 4\varphi, \end{aligned}$$

$$\begin{aligned} x_{\text{Cu III}'} = & 68.92 + 1.02 \cos \varphi - 0.16 \cos 2\varphi - 0.08 \cos 3\varphi \\ & + 0.00 \cos 4\varphi - 1.96 \sin \varphi + 0.01 \sin 2\varphi \\ & + 0.02 \sin 3\varphi + 0.03 \sin 4\varphi, \end{aligned}$$

where φ is the azimuth as read. $x_{\text{Cu III}'}$ is a set of measurements made on crystal III in a different holder.

⁷ M. Owen, Ann. der Physik [4], 37, 657-699 (1912).

⁸ H. J. Seeman and E. Vogt, Ann. der Physik [5], 2, 976-990 (1929).

Figure 2 gives the observations for crystal III plotted as a function of the azimuth φ . The curve drawn is $A_0 + A_1 \cos \varphi + B_1 \sin \varphi$ as determined by the least squares analysis. Due to the fact that it was impossible to secure a holder which was perfectly straight and vertical, the crystal did not rotate exactly about its axis of figure. This gives rise to the large 360° period which the results show. That this is the case is supported by the fact that the 360° periods obtained by the least squares analysis are in close agreement in phase, with the exception of $x_{cu III}'$ which was made, as has been stated, with a different holder. An additional cause which contributes to this 360° period and may explain a shift in phase is the fact that the crystals were not exactly right circular cylinders. Thus we ascribe the whole of the 360° period to instrumental error. It is impossible to assign a crystallographic basis to the 360° period without attributing hemihedry to copper, for which there is, of course, no shadow of evidence.

Fig. 2. Values of the deflection of the beam plotted against the azimuth of the crystal.

If there is any anisotropy, it must have four-fold symmetry about a $\langle 100 \rangle$ axis, three-fold symmetry about a $\langle 111 \rangle$ axis, and two-fold symmetry about a $\langle 110 \rangle$ axis. These are all the symmetry properties of a cubic crystal. Now, if without touching the apparatus we repeat a reading, on the average we will find that it cannot be reproduced closer than 0.5 millimeter. This is indicated on Fig. 2 where the diameter of the circles representing the observations gives what we may call the limits of "immediate reproducibility" of an observation. This represents a sort of minimum probable error. The actual probable error is much larger, as other factors such as the variation of temperature and humidity, which affect the length of the fibers, must be considered in assigning a proper value to the probable error. If we take this value of 0.5 millimeter as the minimum probable error, then we can compute from it the probable error in a coefficient of the Fourier series. For a series, representing 36 observations the probable error of a coefficient of a harmonic term is 0.236 times the probable error of a single observation, i.e., in the present case, 0.12 millimeter.

Now the axis of figure of crystal III lies near a $\langle 100 \rangle$ axis. Hence, if any anisotropy exists, we should expect a large term in 4φ . We see that the coefficient is actually less than half of the minimum probable error of that coefficient, i.e., it is sensibly zero. By the same reasoning the terms in 3φ are also sensibly zero. There is no physical justification for such terms.

In crystal II, whose axis of figure is close to a $\langle 111 \rangle$ axis, we should expect a large term in 3φ . Actually, the 4φ coefficient which has no significance for a three-fold axis, is larger than the 3φ coefficient, and the fact that both coefficients are larger than our minimum probable error should not therefore be taken as significant. We can therefore say that no three-fold symmetry can be detected with any degree of certainty. In a similar way the 3φ and 4φ coefficients of the more unsymmetrical cases of crystals IV and VII may be regarded as negligible.

It is to be noticed that in all cases the terms in 2φ have amplitudes larger than our assigned error. These can all safely be considered as due to the "spread" of the points. That is, we have chosen too small a value to represent our probable error. If we choose an error twice as great, viz., 1.0 millimeter, the probable errors in the 2φ terms become as large as the terms themselves.

We can therefore only ascribe any physical reality to the terms of period 360° , and these, it seems, are wholly due to instrumental defects. To assign a *limit of error* to this work it is only necessary to notice that the coefficients of terms of shorter periods than one revolution are all less than 1 percent of the whole effect, viz., less than about 0.7 millimeter. This represents, of course, not the probable error in a coefficient, but rather a limit of error; the actual probable error is less than this.

It is to be concluded from the experimental work described above that single crystals of copper show no variation of their diamagnetic susceptibility with the direction of the applied magnetic field greater than 1 percent.

The author wishes to express his sincerest appreciation to Dr. L. W. McKeehan for placing the facilities of the Sloane Physics Laboratory at his disposal, and for much helpful guidance and discussion during this work.

TENSION COEFFICIENT OF RESISTANCE OF METALS*

BY HARRY ROLNICK

SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received June 23, 1930)

ABSTRACT

A new method for measuring the change in resistance of a metal under tension has been developed and applied to fifteen metals. A direct current is sent through the wire under test while longitudinal vibrations set up in the wire cause the resistance and consequently the potential drop in the wire to fluctuate. These changes are amplified and measured. In this way it has been found that for bismuth, aluminium, manganin, and constantan the resistance decreases with tension while for all the other metals investigated the resistance increases with tension.

INTRODUCTION

THE change in electrical properties of metals under stress was first investigated by William Thomson, later Lord Kelvin, and described by him in a paper entitled "The Electrodynamical Qualities of Metals."¹ Due to the lack of sensitive apparatus, his experiments, which were conducted on copper and iron, gave untrustworthy results. Soon afterwards, H. Tomlinson,² at Lord Kelvin's suggestion, undertook to determine the exact change in resistance of wires caused by tension along their length. This remains the most extensive investigation on the subject. Other work has been done by W. E. Williams³ on bismuth; by Donaldson and Wilson⁴ on lead; and by N. F. Smith^{5,6} on iron, steel, copper, and brass. The most complete study in recent years has been made by P. W. Bridgman^{7,8,9} on many metals which he had at hand in the form of wires because of previous work on their pressure coefficients of resistance.

The method, a static one, used by all other investigators for studying these effects is to put a known load on the wires and then to measure the corresponding change in resistance. From this change is subtracted that produced by alteration in dimensions. The remainder is considered to be the change in resistance due to the stress.

The object of this research was the development of a dynamic method of

measuring the tension coefficient of resistance and its application to metals whose coefficient is not easily obtained by static measurements. In the method finally adopted, the tension applied is alternating, in order to eliminate spurious effects due to thermoelectric forces and other effects of local or variable heating. A direct current is sent through the wire. As a result of the variations in resistance there are corresponding variations in the potential drop across the wire, and these are impressed on the grid of the first tube of calibrated amplifier, by means of which they are magnified and measured. From these data and the value of the direct current through the wire the change in resistivity due to tension is calculated.

APPARATUS AND PROCEDURE

The wire to be stretched, Fig. 1, is fastened at one end to a brass cylinder which is placed in a holder that can be moved by a screw in the direction of the wire axis to control the tension. The other end is wrapped around a hook. A glass rod, welded to the hook, connects it to the moving arm of a moving

Fig. 1. Diagram of apparatus.

armature loud speaker unit. The hook is held in position by a cross-shaped piece of thin steel cut from an old telephone diaphragm. The ends of this cross are held fast between two brass collars. From them projects a rod which holds the collars securely. This arrangement keeps the motion of the hook axial.

The tension is applied by moving the brass cylinder back by means of the screw, thus stretching the wire. Care must be taken to avoid the production of standing transverse waves which will appear with amplitudes ranging from 1 mm to 5mm if the tension bears the appropriate relation to the length and density of the wire.

The glass rod is put in to insulate the wire from the loud speaker unit. Alternating current of 1025 cycles per second from a tube generator and amplifier is led into the loud speaker coil, and sets the wire into longitudinal vibration with a frequency equal to that of the alternating current. This frequency of current was chosen because it could be conveniently checked by a standard tuning fork making 1024 vibrations per second.

A battery, Fig. 2, sends a direct current through the wire. The change in resistance of the wire changes the potential drop across it, the alternating component is impressed on the grid of a vacuum tube of the amplifier. The choke coil, of 15 henrys inductance, makes the circuit impedance so high that the change in potential drop due to the current change is made negligible.

Fig. 2. Battery arrangement.

Fig. 3 is the wiring diagram of the six-tube resistance coupled amplifier. The amplifier is broken into two sets of three each, each part with its own batteries in a sheet tin box. Unless this is done the amplifier maintains continuous electrical oscillations. The connections to the first three tubes are arranged so that either one, two, or three may be used together with the last

Fig. 3. Wiring diagram of the six tube resistance coupled amplifier.

three. It has been found difficult to get steady amplification without considerable noise with six tubes. Five tubes, with an amplification of about twenty-five thousand, gave very satisfactory performance and this number was used throughout the work. Between the third and fourth stages is fixed a circuit (LC) tuned to 1025 cycles. Its impedance to current of this frequency is five thousand ohms; to all other frequencies its impedance is considerably smaller. Thus it acts as a filter, being a low resistance shunt for all currents of frequencies other than 1025 cycles. Its use makes the amplifier very quiet. The negative side of the B battery and the metal shielding are grounded.

In the last stage is a power tube in the plate circuit of which is a hot-wire vacuum thermocouple (Western Electric No. 232) with an adjustable resist-

ance in series with it. The condenser (*C*) allows only alternating current to go through the thermocouple, which is used in connection with a galvanometer. The phones are used to detect any extraneous disturbance. The amplifier is first calibrated by sending a known e.m.f. into the input circuit and noting the deflections of the galvanometer in the output circuit.

The amplitude of vibration is measured with an optical lever. The back of a small light mirror about five millimeters in diameter is fastened to a tightly drawn fine wire, and the tip of the mirror rests against a small lip (*A* in Fig. 1) projecting from the hook to which the moving end of the vibrating wire is attached. Light from a slit is condensed on the mirror and focussed on a scale. As the lip moves back and forth the mirror is tipped about the wire holding it. The reflected image of the slit is drawn out into a band, whose width is proportional to the amplitude of vibration of the hook and the end of the wire.

One end of the specimen to be measured is fastened to the hook (Fig. 1) and the other end to the brass cylinder. A slight tension is put on the wire. The mirror is moved into such a position that an image of the slit is thrown on the scale. The oscillator is started and the wire forced into longitudinal vibrations, care being taken to avoid transverse vibrations. The amplifier is then switched on and the galvanometer reading noted. Then a small direct current is sent through the wire and the galvanometer reading again noted. This is repeated for different values of the direct current, which never exceeds a tenth of an ampere. The purpose of the several measurements is to decrease the effect of the errors from irregularities in the operation of the amplifier and those due to outside disturbances. Meanwhile the width of the band of light on the scale is observed from time to time. Galvanometer readings are taken only for equal amplitudes of vibration of the end of the wire, as shown by the width of the band of light. Some wires give considerable trouble in that the amplitude of vibration must be carefully adjusted to avoid breaking the wire in case transverse vibrations are set up.

After enough readings are taken the oscillator is stopped and the length of the wire and distance of the mirror axis from the wire are measured. The resistance of the wire is found with a wheatstone bridge.

MATERIALS TESTED AND THEIR METHOD OF PREPARATION

All the wires were either 0.004" or 0.005" in diameter, and all were obtained C.P. from Baker and Co., except molybdenum, tungsten, manganese, constantan, and nichrome. Molybdenum was from the Fansteel Products Co., tungsten from the Lamp Works of the General Electric Co. at Nela Park, manganin (84 Cu 4 Ni 12 Mn), constantan (60 Cu 40 Ni) and nichrome (85 Ni 15 Cr) from the Driver-Harris Co.

Annealing was effected by passing a current through the wire, except in the cases of aluminium and copper. Silver, gold, palladium, and platinum were annealed in air for an hour at a temperature about 300° below their melting points. Aluminium and copper were maintained for two hours at a temperature of 400°C in a steam bath. Molybdenum, tungsten, manganin,

and constantan were annealed in an atmosphere of hydrogen for one hour; manganin and constantan at 700°C, molybdenum at 2000°C, tungsten at 2500°C.

Bismuth, lead, tin and nichrome were not annealed; the first three are self-annealing and nichrome has such a high resistance that a large enough current could not be obtained with the power supply available.

Tin and bismuth were the most difficult to measure both on account of their softness and because the change in potential drop would not remain constant. In the results for these two wires abnormally large errors may be found.

MEASUREMENTS AND CALCULATIONS

Length of wire, distance of scale from mirror, width of light band, resistance of wire, direct current through wire, and galvanometer deflections are the only measured quantities. The first three give the fractional change in length of the wire; the last two enter in the calculations of the change of resistance. From the galvanometer deflection the potential difference impressed on the input of the amplifier is obtained and this equals the product of the direct current by the change in resistance. The fractional change in resistivity is calculated from the following relation:

$$\Delta R/R = (1 + 2w - K) \frac{\Delta l}{l} + \frac{\Delta \rho}{\rho}.$$

where w = Poisson's ratio, K = a constant and l = length of wire.

The factor $(1+2w)\Delta l/l$ is the change in resistance due to alteration of dimensions of the wire. In most cases the values of Poisson's ratio were taken from tables.¹⁰ For some metals this ratio was computed from the compressibility (k) and Young's Modulus (E) for the material. The formula used in $w = 0.5 - Ek/6$. Table I indicates how close the calculated values of

TABLE I.

Moduli for molybdenum and nichrome were measured for this investigation with an apparatus constructed by Mr. L. R. Jackson of this laboratory.

The term $-K\Delta l/l$ is the change in resistance produced by a change in temperature of the wire as it is stretched and released. When a wire is suddenly stretched there will be a fall in temperature if the metal expands when heated and this temperature change is reversible.^{11,12} The change in temperature is given by the formula:

$$\Delta T = -TaP/C_p d$$

The fractional change in resistance due to this change in temperature is

$$\Delta R/R = -K\Delta l/l$$

$$K = abTE/C_p d$$

In these formulae T =absolute temperature; a =thermal coefficient of expansion; P =applied tension; C_p =specific heat; d =density; b =temperature coefficient of resistance; and E =Young's Modulus.

Table II contains the values of w and K used, together with the computed values of $\Delta R/R$, $\Delta\rho/\rho$, and $\Delta\rho/\rho$ divided by $\Delta l/l$.

TABLE II.

The probable error in the resistance measurement, in the length of the wire, usually about sixty centimeters, in the distance of the mirror to the scale, and in the direct current is less than one-half of one percent in each case. The width of the light band, from one to four centimeters, was measured with a probable error of from one to three percent, being higher for smaller widths. The resultant error in the fractional change in length is about of the same magnitude. The probable error in measuring the alternating potential difference is dependent on the accuracy with which the amplifier has been calibrated and on the steadiness of the galvanometer deflections.

¹¹ W. V. Houston, Introduction to Mathematical Physics, p. 192.

¹² P. G. Nutting, Jour. Wash. Acad. of Sci. 19, 109-115 (1929).

The calibration is accurate to one percent, and the precision of the galvanometer reading is within two percent except in the measurements on bismuth and tin. For these metals, the galvanometer deflections were so unsteady as to cause a probable error of about ten percent in the potential difference measured.

Into the calculations there enter the thermal expansion coefficient, the temperature coefficient of resistance, the specific heat, Young's modulus and the density, all in correction terms, while Poisson's ratio enters directly. The uncertainty in the values of these constants varies considerably from metal to metal. The constants entering indirectly contribute about two percent to the uncertainty while Poisson's ratio can not be relied on within five percent. Thus the final results have errors of about seven percent due to constants used in calculating. Improved values of these constants will permit correspondingly greater accuracy in the final results. The measured quantities contribute about three percent more so that the possible error of the results is about ten percent. In the case of bismuth and tin the possible error is about 20 percent.

TABLE III. $\Delta\rho/\rho$ for a tension of 1 kg/cm^2 by different observers.

Metal	Bridgman	Tomlinson	Rolnick
Aluminium	$+1.8 \times 10^{-6}$	-0.63×10^{-6}	-0.96×10^{-6}
Silver	+3.4	+2.07	+2.51
Gold	+3.87		+2.86

Lead		+9.75	+7.0
Palladium	+1.66		+2.44
Platinum	+1.56	+2.25	+2.08
Tin		+5.89	+10.6
Zinc		+2.75	+3.26
Manganin	-.76		-.91

For bismuth, W. E. Williams gives $\Delta R/R = -53.5 \times 10^{-6}$ while the writer obtains $\Delta R/R = -28.1 \times 10^{-6}$.

In Table III is a comparison of my results with those of other investigators. These results have all been reduced to fractional changes of resistivity with a tension of 1 kg/cm^2 , using the values of Young's Modulus mentioned above. Considering the wide variation between the results of other workers, the present results tally fairly well with theirs.

The writer is deeply indebted to Professor L. W. McKeehan for his suggestion of the problem and for his advice and encouragement during its progress.

VIBRATIONS OF A NON-PLANAR MEMBRANE

BY GEORGE R. STIBITZ

CORNELL UNIVERSITY

(Received June 16, 1930)

ABSTRACT

Equations of motion are deduced for a non-planar membrane in small oscillation about any position of equilibrium. Cylindrical and conical membranes are discussed briefly as special cases; with certain types of boundary conditions there is no solution of the problem when stiffness is entirely omitted, and this is particularly true of the cone because of a characteristic singular point in the differential equations.

1. INTRODUCTION

NUMEROUS investigators have published studies of the vibrations of the plane membrane, including besides the usual circular drumhead the square, triangular and other shaped drumheads of uniform surface density and also the loaded drum, in which the density of the membrane is not uniform. Two articles in recent years have treated the statics of non-planar membranes, and to these the present writer is much indebted. They are the articles of Max Lagally¹ and of Frank Löbell.²

In this paper we will consider the problem of a membrane with very large elastic constants, whose middle surface is analytic and whose mass is uniformly distributed over that surface. We obtain the equations of motion for a general surface of this type as a system of three linear partial second-order differential equations. As a special case, we consider a type of symmetric vibration of a surface of revolution and finally the vibrations of a cone. In each case the vibrations are considered to take place about a strained equilibrium position of the membrane.

Let the middle surface of the membrane be described by a variable vector, r , drawn from any fixed point as origin. We can write r as a function of two parameters. Since the surface is analytic, it can be shown³ that the parameters, say u_1 and u_2 , can be so chosen that the lines described by the vector r when u_1 is constant and when u_2 is constant, respectively, are the orthogonal "lines of principal-curvature" of the surface.

Suppose that in such a surface tangential forces act. We define the stress component across any parametric curve u_1 (i.e. a curve along which u_2 is constant) as the vector force per unit length exerted by the "positive" part of the surface on the "negative" part across that curve. By "positive" part of the surface with respect to the curve $u_2 = K$, we mean that part defined by the inequality $u_2 > K$. The stress component across the u_1 curves we name σ_2 , and that across the u_2 curves, σ_1 .

¹ Max Lagally, *Zeits. f. Angewandte Math. u. Mech.* **4**, 377 (1924).

² Frank Löbell, *Zeits. f. Angewandte Math. u. Mech.* **7**, 463 (1927).

³ Blaschke, *Vorlesungen über Differentialgeometrie*, p. 62.

Let t_1, t_2 be the unit tangents along the u_1, u_2 curves respectively. If we assume the membrane to be perfectly pliable, then the stresses will lie entirely in the plane of t_1, t_2 . Their four scalar components in these directions we define by the vector equations,

$$\sigma_1 = \sigma_{11}t_1 + \sigma_{12}t_2, \quad \sigma_2 = \sigma_{21}t_1 + \sigma_{22}t_2. \quad 1.1$$

2. THE A, B AND C CONDITIONS OF THE MEMBRANE

For convenience in manipulation we define three states or conditions of the membrane. The first of these, state A , is the totally unstrained state. We will also refer to the middle surface of the membrane in this state as the surface A .

Next, let the membrane be stretched in any manner by forces exerted across its boundaries, and let it come to rest. Each element of the surface will then be in equilibrium under the stress forces acting tangentially across its own boundary. Call this state, B .

Finally, let the membrane undergo a small displacement from its equilibrium position B to a third position C . This last will not in general be an equilibrium position, the stress forces exerting a force P per unit area. The elastic constants for the displacement BC may be slightly different from those for AB ; call Young's modulus and Poisson's ratio for BC , E and κ respectively.

Let parametric lines u_1, u_2 as described in Sec. 1 be drawn on the surface B , these curves remaining fixed in space when the membrane moves to position C . Let v_1, v_2 be the parametric lines for the actual middle surface of the membrane, these lines moving with the membrane. We will so choose v_1, v_2 that when the membrane is in position B , v_1, v_2 coincide with u_1, u_2 .

Since we have assumed the elastic constants of the membrane to be large, the forces arising from displacements of the particles near a point p fixed in the middle surface can be assumed to be only those due to elastic strain of the element as long as the displacements lie in the tangent plane at p . Hence we can neglect the effect of rotation of the element when the axis of this rotation is perpendicular to the surface at p , for this type of displacement produces no strain in the element and the forces due to changes in the directions of the initial stresses will be negligible in comparison with forces due to the strains. On the other hand, displacements perpendicular to the surface do not produce strains in the element to the first order, and the only forces called into existence by such a displacement are those due to the changed directions of the initial stresses. Consequently we cannot neglect the component of rotation of the element which lies in the tangent plane.

3. THE ADDED STRESSES

Suppose q is a point on the middle surface near to p , both points moving with the membrane. Let q' and p' be the positions occupied by q and p when the membrane is in state B . Let t be the vector obtained by dividing the vector pq by the constant scalar $p'q'$ and then letting q approach p .

Then

$$t = \frac{\partial r}{\partial s}, \quad 3.1$$

where s represents arc length in the direction pq . In position C this tangent vector is different in magnitude and direction from the corresponding vector in position B ; let the difference vector be δt . Then evidently, if \bar{r} is the vector of the displacement BC , we have

$$\delta t = \frac{\partial \bar{r}}{\partial s}, \quad \delta t_1 = \frac{\partial \bar{r}}{\partial s_1}, \quad \delta t_2 = \frac{\partial \bar{r}}{\partial s_2}, \quad 3.2$$

in which the subscripts refer to cases in which pq lies along one of the coordinate lines.

Now in general the element about p undergoes a translation, a pure strain, and a rotation; let g denote the vector rotation and write with the usual notation for the components of strain:

$$\delta t_1 = g \times t_1 + \delta \epsilon_{11} t_1 + \delta \epsilon_{12} t_2, \quad 3.3$$

$$\delta t_2 = g \times t_2 + \delta \epsilon_{12} t_1 + \delta \epsilon_{22} t_2. \quad 3.4$$

Taking the scalar products $t_1 \cdot$, $t_2 \cdot$, with 3.3 and 3.4 and combining, we get, using 3.2,

$$\frac{\partial \bar{r}}{\partial s_1} \cdot t_1 = \delta \epsilon_{11}; \quad \frac{\partial \bar{r}}{\partial s_2} \cdot t_2 = \delta \epsilon_{22}; \quad 3.5$$

$$\frac{\partial \bar{r}}{\partial s_1} \cdot t_2 + \frac{\partial \bar{r}}{\partial s_2} \cdot t_1 = g \times t_1 \cdot t_2 + g \times t_2 \cdot t_1 + \delta \epsilon_{12} + \delta \epsilon_{21}. \quad 3.6$$

Noting that $g \times t_1 \cdot t_2 = -g \times t_2 \cdot t_1$ and $\delta \epsilon_{12} = \delta \epsilon_{21}$, we have

$$2\delta \epsilon_{12} = \frac{\partial \bar{r}}{\partial s_1} \cdot t_2 + \frac{\partial \bar{r}}{\partial s_2} \cdot t_1. \quad 3.7$$

Following the method of Lagally⁴ and Love⁵ except that we deal with two dimensions instead of three, we obtain the following formulas for the stresses in terms of the strains and the elastic constants:

$$\delta \sigma_{11} = 2\mu \delta \epsilon_{11} + \lambda(\delta \epsilon_{11} + \delta \epsilon_{22}), \quad 3.8$$

$$\delta \sigma_{12} = \delta \sigma_{21} = 2\mu \delta \epsilon_{12}, \quad 3.9$$

$$\delta \sigma_{22} = 2\mu \delta \epsilon_{22} + \lambda(\delta \epsilon_{11} + \delta \epsilon_{22}), \quad 3.10$$

where

$$\lambda = \frac{\kappa E \tau}{1 - \kappa^2}, \quad \mu = \frac{E \tau}{2(1 + \kappa)}. \quad 3.11$$

τ being the thickness of the membrane.

⁴ Lagally, Vektorrechnung, p. 260.

⁵ Love, Elasticity, p. 98-101.

4. FORCES ACTING ON THE MEMBRANE IN POSITION *C*.

It will be recalled that for the purpose of calculating the changes in stress due to rotation of the tangent plane we need consider only that component of the tangent variation which is normal to the surface; let this component of δt_1 and δt_2 be

$$\delta' t_1 = t_1 \left(\frac{\partial \bar{r}}{\partial s_1} \cdot t_3 \right), \quad \delta' t_2 = t_2 \left(\frac{\partial \bar{r}}{\partial s_2} \cdot t_3 \right). \quad 4.1, 4.2$$

Then the total vector stresses in position *C* are:

$$\text{across } v_2 \quad \bar{\sigma}_1 = (\sigma_{11} + \delta\sigma_{11})(t_1 + \delta' t_1) + (\sigma_{12} + \delta\sigma_{12})(t_2 + \delta' t_2), \quad 4.3$$

$$\text{across } v_1 \quad \bar{\sigma}_2 = (\sigma_{21} + \delta\sigma_{21})(t_1 + \delta' t_1) + (\sigma_{22} + \delta\sigma_{22})(t_2 + \delta' t_2), \quad 4.4$$

or, dropping second order terms, by 1.1,

$$\bar{\sigma}_1 = \sigma_1 + \sigma_{11}\delta' t_1 + t_1\delta\sigma_{11} + \sigma_{12}\delta' t_2 + t_2\delta\sigma_{12}, \quad 4.5$$

$$\bar{\sigma}_2 = \sigma_2 + \sigma_{21}\delta' t_1 + t_1\delta\sigma_{21} + \sigma_{22}\delta' t_2 + t_2\delta\sigma_{22}. \quad 4.6$$

The conditions for equilibrium between the stress forces and the surface forces can be obtained by direct consideration in the usual manner of an element bounded by parameter lines, or by the method of Löbell.² The conditions are given by the vector equation,

$$\left(G_1 - \frac{\partial}{\partial s_2} \right) \bar{\sigma}_2 + \left(G_2 - \frac{\partial}{\partial s_1} \right) \bar{\sigma}_1 + P = 0, \quad 5.1$$

where the G 's are the geodesic curvatures as defined below (6.2) and $-P$ is the external surface force per unit area.

Let

$$\delta\sigma_1 = \bar{\sigma}_1 - \sigma_1, \quad \delta\sigma_2 = \bar{\sigma}_2 - \sigma_2. \quad 5.2$$

Then, in position *C*,

$$-P = \left(G_1 - \frac{\partial}{\partial s_2} \right) (\sigma_2 + \delta\sigma_2) + \left(G_2 - \frac{\partial}{\partial s_1} \right) (\sigma_1 + \delta\sigma_1). \quad 5.3$$

But in position *B*, P is zero, i.e.

$$\left(G_1 - \frac{\partial}{\partial s_2} \right) \sigma_2 + \left(G_2 - \frac{\partial}{\partial s_1} \right) \sigma_1 = 0. \quad 5.4$$

Hence in position *C*

$$-P = \left(G_1 - \frac{\partial}{\partial s_2} \right) \delta\sigma_2 + \left(G_2 - \frac{\partial}{\partial s_1} \right) \delta\sigma_1. \quad 5.5$$

5. SCALAR COMPONENTS OF $\delta\sigma_i$ AND OF P

Assume as basic vectors the unit vectors t_1 and t_2 introduced in Sec. 1, and define $t_3 = t_1 \times t_2$. Define the components of \bar{r} , the vector of displacement BC , by

$$\bar{r} = r_1 t_1 + r_2 t_2 + r_3 t_3, \quad 6.1$$

and the normal and geodesic curvatures of the parametric lines by

$$\begin{aligned} N_1 &= -\frac{\partial t_1}{\partial s_1} \cdot t_3 = \frac{\partial t_3}{\partial s_1} \cdot t_1, & N_2 &= -\frac{\partial t_2}{\partial s_2} \cdot t_3 = \frac{\partial t_3}{\partial s_2} \cdot t_2, \\ G_1 &= \frac{\partial t_1}{\partial s_1} \cdot t_2 = -\frac{\partial t_2}{\partial s_1} \cdot t_1, & G_2 &= \frac{\partial t_2}{\partial s_2} \cdot t_1 = -\frac{\partial t_1}{\partial s_2} \cdot t_2. \end{aligned} \quad 6.2$$

The geodesic torsion, $(\delta t_1 / \delta s_2) \cdot t_3$, is zero for lines of principal curvature, as are also the scalar product of a unit vector and its derivative. Substituting from 6.1 and 6.2 in 4.1 and 4.2, we see that

$$\delta' t_1 = \left(\frac{\partial r_3}{\partial s_1} - r_1 N_1 \right) t_3, \quad \delta' t_2 = \left(\frac{\partial r_3}{\partial s_2} - r_2 N_2 \right) t_3. \quad 6.3$$

Similarly from 3.8–3.11, 3.5, 3.6, 6.1, 6.2, we have the result:

$$\delta\sigma_{11} = (2\mu + \lambda) \left(\frac{\partial r_1}{\partial s_1} - r_1 G_1 + r_3 N_1 \right) + \lambda \left(\frac{\partial r_2}{\partial s_2} - r_2 G_2 + r_3 N_2 \right), \quad 6.4$$

$$\delta\sigma_{22} = (2\mu + \lambda) \left(\frac{\partial r_2}{\partial s_2} - r_2 G_2 + r_3 N_2 \right) + \lambda \left(\frac{\partial r_1}{\partial s_1} - r_1 G_1 + r_3 N_1 \right), \quad 6.5$$

$$\delta\sigma_{12} = \mu \left(\frac{\partial r_1}{\partial s_2} + \frac{\partial r_2}{\partial s_1} + r_1 G_1 + r_2 G_2 \right). \quad 6.6$$

Comparing these results with 4.5, 4.6 and 5.2 we obtain finally:

$$\begin{aligned} \delta\sigma_1 &= \sigma_{11} \left(\frac{\partial r_3}{\partial s_1} - r_1 N_1 \right) t_3 + \left[(2\mu + \lambda) \left(\frac{\partial r_1}{\partial s_1} - r_1 G_1 + r_3 N_1 \right) \right. \\ &\quad \left. + \lambda \left(\frac{\partial r_2}{\partial s_2} - r_2 G_2 + r_3 N_2 \right) \right] t_1 + \sigma_{12} \left(\frac{\partial r_3}{\partial s_2} - r_2 N_2 \right) t_3 \\ &\quad + \mu \left(\frac{\partial r_1}{\partial s_2} + \frac{\partial r_2}{\partial s_1} + r_1 G_1 + r_2 G_2 \right) t_2. \end{aligned} \quad 6.7$$

Interchange of the subscripts 1 and 2 in 6.7 gives us the equation for $\delta\sigma_2$.

Substituting these results in the equation for P , (5.5), and carrying through the necessary algebra, we have P , the force per unit area due to the stresses, expressed in terms of components along the vectors t_i . Define the scalar components of P by

$$P = P_1 t_1 + P_2 t_2 + P_3 t_3. \quad 6.8$$

Resolving P into its components, we have ultimately:

$$\begin{aligned}
 P_1 = & -r_1 \left[2\mu G_1^2 + \lambda \frac{\partial G_2}{\partial s_1} + \sigma_{11} N_1^2 + 2\mu G_2^2 - \mu \frac{\partial G_1}{\partial s_2} \right] \\
 & - r_2 \left[(2\mu + \lambda) \frac{\partial G_1}{\partial s_1} + \sigma_{12} N_1 N_2 - \mu \frac{\partial G_2}{\partial s_2} \right] \\
 & + r_3 \left[(2\mu + \lambda) \frac{\partial N_1}{\partial s_1} + \lambda \frac{\partial N_2}{\partial s_1} + 2\mu G_2 (N_2 - N_1) \right] \\
 & - G_2 (2\mu + \lambda) \frac{\partial r_1}{\partial s_1} - \mu G_1 \frac{\partial r_1}{\partial s_2} - (4\mu + \lambda) \frac{\partial r_2}{\partial s_1} + 3\mu G_2 \frac{\partial r_2}{\partial s_2} \\
 & + [\lambda N_2 + (2\mu + \lambda) N_1] \frac{\partial r_3}{\partial s_1} + N_1 \sigma_{12} \frac{\partial r_3}{\partial s_2} + N_1 \sigma_{11} \frac{\partial r_3}{\partial s_1} \\
 & + (2\mu + \lambda) \frac{\partial^2 r_1}{\partial s_1^2} + \mu \frac{\partial^2 r_1}{\partial s_2^2} + \mu \frac{\partial^2 r_2}{\partial s_2 \partial s_1} + \lambda \frac{\partial^2 r_2}{\partial s_1 \partial s_2},
 \end{aligned} \tag{6.9}$$

from which P_2 is found by interchange of subscripts 1 and 2;

$$\begin{aligned}
 P_2 = & r_1 \left[N_1 G_1 \sigma_{12} + N_1 G_2 (\lambda + \sigma_{11}) + N_2 G_2 (2\mu + \lambda) - \sigma_{11} \frac{\partial N_1}{\partial s_1} - \sigma_{12} \frac{\partial N_1}{\partial s_2} \right. \\
 & \left. - N_1 \left(\frac{\partial \sigma_{11}}{\partial s_1} + \frac{\partial \sigma_{12}}{\partial s_2} \right) \right] + r_2 \left[N_2 G_2 \sigma_{12} + N_2 G_1 (\lambda + \sigma_{22}) + N_1 G_1 (2\mu + \lambda) \right. \\
 & \left. - \sigma_{22} \frac{\partial N_2}{\partial s_2} - \sigma_{12} \frac{\partial N_2}{\partial s_1} - N_2 \left(\frac{\partial \sigma_{22}}{\partial s_2} + \frac{\partial \sigma_{12}}{\partial s_1} \right) \right] - r_3 [(2\mu + \lambda) (N_1^2 + N_2^2) \\
 & + 2\lambda N_1 N_2] - \frac{\partial r_1}{\partial s_1} [N_1 (2\mu + \lambda + \sigma_{11}) + N_2 \lambda] - N_1 \sigma_{12} \frac{\partial r_1}{\partial s_2} \\
 & - N_2 \sigma_{12} \frac{\partial r_2}{\partial s_1} - \frac{\partial r_2}{\partial s_2} [N_1 \lambda + N_2 (2\mu + \lambda + \sigma_{22})] + \frac{\partial r_3}{\partial s_1} \left[\frac{\partial \sigma_{11}}{\partial s_1} + \frac{\partial \sigma_{12}}{\partial s_2} \right. \\
 & \left. - G_1 \sigma_{12} - G_2 \sigma_{11} \right] + \frac{\partial r_3}{\partial s_2} \left[\frac{\partial \sigma_{22}}{\partial s_2} + \frac{\partial \sigma_{12}}{\partial s_1} - G_2 \sigma_{12} - G_1 \sigma_{22} \right] \\
 & + \sigma_{11} \frac{\partial^2 r_3}{\partial s_1^2} + \sigma_{12} \left(\frac{\partial^2 r_3}{\partial s_1 \partial s_2} + \frac{\partial^2 r_3}{\partial s_2 \partial s_1} \right) + \sigma_{22} \frac{\partial^2 r_3}{\partial s_2^2}.
 \end{aligned}$$

6. EQUATIONS OF MOTION

The equations we have deduced are valid for any small displacement \bar{r} . If \bar{r} is a function of time, then P is also a function of time. We may suppose that at each instant each element of the membrane is vibrating under the influence of the tangential stress-forces P and the resistive forces due to the radiation of energy and to internal friction. Then the sum of the real forces acting on the element must be equal to the effective forces. Suppose

the resistive forces to be proportional to the velocity, $\dot{\bar{r}} = \delta \bar{r} / \delta t$. We can then write,

$$P - R\dot{\bar{r}} - m\ddot{\bar{r}} = 0, \quad R = \text{const.} > 0. \quad 7.1$$

The three scalar equations implied by 7.1 together with the value of P obtained from 6.9 and 6.10 furnish us with the required system of partial differential equations of motion of a general surface.

Let us seek normal vibrations of the form

$$\bar{r} = \rho e^{i p t}. \quad 7.2$$

Substituting in 7.1,

$$P^* - R i p \rho + m p^2 \rho = 0, \quad 7.3$$

where P^* is the function obtained by replacing each component of \bar{r} in P by the corresponding component of ρ . Equation 7.3 is then the equation for the amplitudes of the normal modes of vibration of the general surface.

7. APPLICATIONS TO SURFACES OF REVOLUTION

For the surface of revolution we choose as coordinates, (1) distance measured from the origin along a generator, $u_1 = s_1$, (2) the angle of revolution from a fixed plane, u_2 . If we consider only vibrations in which r_2 is zero, and in which r_1 and r_2 are functions of u_1 alone, then the amplitude equations become:

$$\begin{aligned} & -\rho_1 \left[\lambda \frac{\partial G_2}{\partial u_1} + \sigma_{11} N_1^2 + 2\mu G_2^2 + R i p - m p^2 \right] \\ & + \rho_3 \left[(2\mu + \lambda) \frac{\partial N_1}{\partial u_1} + \frac{\partial N_2}{\partial u_1} + 2\mu (N_2 - N_1) G_2 \right] \end{aligned} \quad 8.1$$

$$\begin{aligned} & - \frac{\partial \rho_1}{\partial u_1} G_2 (2\mu + \lambda) + \frac{\partial \rho_3}{\partial u_1} [\lambda N_2 + (2\mu + \lambda) N_1] + \sigma_{11} N_1 \frac{\partial \rho_3}{\partial u_1} + \frac{\partial^2 \rho_1}{\partial u_1^2} (2\mu + \lambda) = 0, \\ & \rho_1 \left[N_1 G_2 (\lambda + \sigma_{11}) + N_2 G_2 (2\mu + \lambda) - \frac{\partial N_1}{\partial u_1} \sigma_{11} - N_1 \frac{\partial \sigma_{11}}{\partial u_1} \right] \\ & - \rho_3 [(2\mu + \lambda) (N_1^2 + N_2^2) + 2\mu N_1 N_2 + R i p - m p^2] \\ & - \frac{\partial \rho_1}{\partial u_1} [N_1 (2\mu + \lambda + \sigma_{11}) + N_2 \lambda] + \frac{\partial \rho_3}{\partial u_1} \left[\frac{\partial \sigma_{11}}{\partial u_1} - G_2 \sigma_{11} \right] + \frac{\partial^2 \rho_3}{\partial u_1^2} \sigma_{11} = 0, \end{aligned} \quad 8.2$$

and the curvatures are,

$$N_1 = - \frac{y''}{(1 - y'^2)^{1/2}}, \quad N_2 = \frac{(1 - y'^2)^{1/2}}{y}; \quad G_1 = 0, \quad G_2 = - \frac{y'}{y}; \quad 8.3$$

where y is the ordinate of the generating curve, expressed as a function of u_1 , and the primes mean the ordinary derivative with respect to u_1 .

The equations for the cone are still simpler, for $y = u_1 \sin \alpha$, 2α being the

angle of the cone, and one easily sees that for equilibrium $\sigma_{11} = \text{const.}/u_1 = c/u_1$, so that the equations become, if $R=0$:

$$\frac{\partial^2 \rho_1}{\partial u_1^2} + \frac{1}{u_1} \frac{\partial \rho_1}{\partial u_1} + \frac{\kappa a}{u_1} \frac{\partial \rho_3}{\partial u_1} - \frac{a}{u_1^2} \rho_3 + \left(q^2 - \frac{1}{u_1^2} \right) \rho_1 = 0, \quad 8.4$$

$$\frac{c}{(2\mu + \lambda)u_1} \frac{\partial^2 \rho_3}{\partial u_1^2} - \frac{\kappa a}{u_1} \frac{\partial \rho_1}{\partial u_1} + \left(q^2 - \frac{a^2}{u_1^2} \right) \rho_3 - \frac{a}{u_1^2} \rho_1 = 0, \quad 8.5$$

where $a = \cot \alpha$, $q^2 = m p^2 / (2\mu + 2)$, m mass per unit area of the membrane. Let us introduce the new variable z for qu ; then, using primes here to denote differentiation with respect to z , we have,

$$\rho_1'' + \frac{1}{z} \rho_1' + \frac{\kappa a}{z} \rho_3' + \left(1 - \frac{1}{z^2} \right) \rho_1 - \frac{a}{z^2} \rho_3 = 0, \quad 8.4b$$

$$\rho_3'' - \frac{\lambda a}{eq} \rho_1' - \frac{2\mu + \lambda}{cq} \frac{a}{z} \rho_1 + \frac{2\mu + \lambda}{cq} \left(z - \frac{a^2}{z} \right) \rho_3 = 0. \quad 8.5b$$

If we suppose the initial stress to be different from zero everywhere in the range we are considering, then it is possible, by taking each of the first derivatives as a new dependent variable, to form a system of four simultaneous first-order differential equations, each of which has on the left side a different first derivative and on the right only an algebraic expression in the four unknowns; the right hand sides of these equations are all homogeneous and the coefficients of the unknowns are bounded and continuous for u greater than zero. Under these conditions it can be shown that four linearly independent continuous solutions exist throughout the range for which z is greater than zero. As is usual in vibration problems, there exists a discrete set of values of z , and so of p , for which the boundary conditions can be satisfied. In any given numerical case these can be found by numerical integration.

If, however, the initial stress is zero, i.e. $c=0$, then ρ_3'' disappears from 8.5b and it is not possible to throw the equations into the form specified above. If we then eliminate ρ_3 from 8.4b and 8.5b we obtain for ρ_1 a differential equation of the second order only, so that for ρ_1 we have only two index solutions and ρ_3 is given by 8.5b in terms of these. There are thus, in general, not enough independent solutions to satisfy the boundary conditions. Furthermore, the coefficients in the equation so obtained for ρ_1 , which is rather complicated and will not be written down here, has two pairs of singular points, one at $z^2 = a^2$, and the other at $z^2 = a^2(1 - \kappa^2)$. It is necessary to examine the solution for ρ_1 at these points by means of a series; we omit the rather tedious details and outline the result. In the region about $z=a$ we find that the indicial equation has the two roots 0 and 2. These differ by an integer, so that we can be certain of only one analytic solution through the point, but we find by actual calculation of the first three terms of the series that there are in fact two independent solutions, since if we use the zero root the second power of z has an arbitrary coefficient. Hence $z=a$ is

not an irregular singular point. Making the same kind of an examination of the point $z = a(1 - \kappa^2)^{\frac{1}{2}}$, however, we find the roots of the indicial equation to be 0 and 0. We can apply the usual method for finding the second solution⁶ and find for it

$$\bar{\rho}_1 = \rho_1 \int \frac{(z^2 - a^2)}{(z^2 - a^2 + a^2 \kappa^2)} \frac{dz}{z \rho_1^2}. \quad 8.6$$

This solution obviously has a pole of the first order at the point under consideration. Hence there is one and only one solution that is continuous throughout the range, $u_1 > 0$. Furthermore, although ρ_1 is continuous through the point $z = a$, yet ρ_3 is discontinuous there, for upon solving for ρ_3 in 8.5 we have

$$\rho_3 = a \frac{\rho_1 + \kappa z \rho_1'}{z^2 - a^2}, \quad 8.7$$

from which it is evident that ρ_3 has a pole of first order at this point.

Although it was thus impossible to obtain an actual solution from the equations for the case of a cone without initial stress, it seemed desirable to obtain a rough idea of what the vibrations may be like. Accordingly, the series for ρ_1 was evaluated near $z = a(1 - \kappa^2)^{\frac{1}{2}}$ for the case of a paper cone with a vertical angle of 120 degrees ($a = 0.58$) and the solution was then carried to $z = 7$ by numerical integration. The shape of the solution thus found suggests comparison with a sine curve. For very great distances out along the cone, 8.4b reduces to, $\rho_1'' + \rho_1 = 0$, so that ρ_1 approaches $\sin z$ while $\rho_3 \rightarrow 0$, which is simply the solution for a plane membrane of the same material. With this function as our norm, we find that the numerical solution, after vanishing at $z = 0.78$, showed a first node-to-loop distance of about 1.0 times the quarter wave-length for the plane longitudinal vibrations of the same frequency; the next succeeding node-to-loop distances were very roughly 1.2, 1.0 and 1.1 times the normal quarter-wave length. The second loop had an amplitude about two-thirds that of the first. Comparison might also be made with Bessel's function, for the equation differs markedly from

$$\rho_1'' + \frac{1}{z} \rho_1' + \rho_1 = 0$$

only within the first half wave or so and approximates to it very closely indeed beyond the first wave-length. The simplest solution of this equation $J_0(z)$ or Bessel's function of order zero, is very similar to the curve found here; the first two loops have an amplitude ratio of 3/4 as against 2/3 for the curve found for ρ_1 but this difference is in part due to their being displaced half a loop outward.

The singular point, $z = a(1 - \kappa^2 \alpha)^{\frac{1}{2}}$ occurs for ordinary materials where the distance from the axis along a line drawn perpendicular to the surface of the cone is about a seventh of a wave-length.

⁶ Ince, Ordinary Differential Equations, p. 22.

Because of the complexity of the equations of the cone it is difficult to examine the effect of reducing the basic stress. A case which is simple enough to handle mathematically, and which may suggest what happens to the vibrating cone under similar conditions, is the circular cylinder. For this membrane the equations are:

$$\rho_1'' + h\kappa\rho_3' + q^2\rho_1 = 0, \quad k\rho_3'' - h\kappa\rho_1' + (q^2 - h^2)\rho_3 = 0,$$

where k is the tension divided by $2\mu + \lambda$ and $1/h$ is the radius of the cylinder. Since all the coefficients are constants, we can assume a solution of the form,

$$\rho_1 = e^{nu_1}, \quad \rho_3 = \zeta e^{nu_1}.$$

We find that

$$\zeta = -\frac{n^2 + q^2}{h\kappa n}$$

and we obtain for n two pairs of solutions, of which one is independent of k to the first order whereas the other becomes infinite as k approaches zero: $n = q\{(q^2 - h^2)/[(1 - n^2)h^2 - q^2]\}^{1/2}$ or $\{(1 - \eta^2)h^2 - q^2\}/k^{1/2}$. As an illustration of the problem with boundary conditions, let the membrane be rigidly fixed at $u=0$ and $u=1$. We now find a variety of different modes of vibration, in fact, the spectrum of characteristic frequencies consists of three different ranges. There is an infinity of modes with frequencies such that $q^2 < h^2(1 - \kappa^2)$, which we may call the low-frequency range; and also an infinity of frequencies given by $q^2 > h^2$, called the high-frequency range; solutions corresponding to intermediate frequencies also exist, but whether they could be made to satisfy these boundary conditions was not definitely determined. The low-frequency modes with positive tension and the high-frequency modes with negative tension are found to be of the form, $n = \pm n_1 i$ or $\pm n_2$ and

$$\rho_1 = C \left[\sin(n_1 u_1 + \gamma) + \frac{n_1 \kappa^2 h^2}{n_2 (q^2 - h^2)} (e^{-n_2 u_1} \pm e^{-n_2 (1-u_1)}) \right],$$

$$\rho_3 = -\frac{n_1 \kappa h}{q^2 - h^2} C [\cos(n_1 u_1 + \gamma) - e^{-n_2 u_1} \pm e^{-n_2 (1-u_1)}].$$

As the basic stresses approach zero and $n_2 \rightarrow \infty$, we note that ρ_3 remains finite relative to ρ_1 ; the effect of the stress as seen in the exponential terms is merely to reduce ρ_3 rapidly to zero at the ends. That is, with vanishing stress the oscillations take on the form obtained from the differential equation for zero stress, while the boundary conditions for ρ_3 are satisfied by means of an added sharp kink at each end.

On the other hand, the high-frequency modes under tension, and the low-frequency modes under compression are of the form, with $n = \pm n_1 i$ or $\pm n_2$

$$\rho_1 = C_1 \sin(n_1 u_1 + \gamma_1) + C_2 \sin(n_2 u_1 + \gamma_2),$$

$$\rho_3 = b_1 C_1 \cos(n_1 u_1 + \gamma_1) + b_2 C_2 \cos(n_2 u_1 + \gamma_2).$$

The second pair of terms in this case represent a short-wave "crinkle" superposed upon the main wave-form represented by the first terms. In this case, as the basic stress vanishes, the wave-length of the crinkle approaches zero, but it appears that its amplitude does not vanish relative to the main wave.

The question obviously presents itself as to how the physical cylindrical membrane with fixed ends and without stress actually vibrates. We may suspect that the slight stiffness which such a membrane must actually possess takes the place of the small basic stress used above and that the modes actually found would have either a superposed crinkle throughout the length of the cylinder or a sharp kink at the ends, similar to what we have found by our analysis.

It seems possible that the difficulties which were encountered above in the case of the cone are in practice surmounted in a similar manner.

The writer wishes to acknowledge the assistance given by Professor E. H. Kennard during the preparation of this paper, especially in the latter part of the article, that dealing with the cylindrical membrane.

CAPILLARY RETENTION OF LIQUIDS IN ASSEMBLAGES OF HOMOGENEOUS SPHERES

BY W. O. SMITH, PAUL D. FOOTE AND P. F. BUSANG
GULF RESEARCH LABORATORY, PITTSBURGH, PA.

(Received June 16, 1930)

ABSTRACT

The pore space in an assemblage of uniform spheres was initially filled with liquid. After very slow drainage the amount of liquid retained by the spheres was experimentally measured. The liquid is retained in the form of rings at the contacts of adjacent spheres. The radii of curvature of the ring surfaces are computed in terms of surface tension, grain radius and pressure drop across the liquid-vapor interface, permitting calculation of the volume retained per sphere contact. The number of contacts per unit volume of spheres is obtained from porosity measurements using the theory developed earlier. Computed and observed data on total volume of retained liquid are in agreement.

IF THE pore spaces in an assemblage of spheres be completely filled by a liquid which is then allowed to drain, a portion of the liquid is retained. The retention occurs during the passage of the liquid-gas interface through the grain assemblage. It is current opinion, as expressed in the semi-technical literature, that such liquid remains in the form of a fairly uniform layer which envelops the separate grains. In order to account for the observed retention, the thickness of the layer would have to be several thousand molecular diameters. Molecular forces, however, decrease extremely rapidly with distance, and unless chemical reactions, such as those involving gel formation, take place, layers exceeding three molecular diameters are improbable. Much of the work on retention has been done with comparatively fine sands and the actual mechanism of the phenomenon has escaped notice. Under the microscope, however, one may readily observe that a small ring of liquid is retained at the point of contact of two spheres. This type of retention is easily demonstrated by dipping two small balls or shot in a liquid and observing the retained liquid when the spheres, in contact, are withdrawn. It also follows from thermodynamical considerations that the major retention occurs in this manner. Equilibrium requires a minimum of free energy, and when the spheres are sufficiently small that gravitational effects are negligible, a given amount of retained fluid must be so distributed that the surface energy is a minimum. This occurs when the liquid is collected about the points of contact of the spheres.

The ring volume can be calculated approximately. Consider a capillary ring of liquid as shown in Fig. 1 with the two principal radii of curvature y and R taken as positive numbers. Complete wetting or zero contact angle with the spheres is assumed. Let Δp be the difference in pressure just outside and inside the liquid surface, and let σ be the surface tension. Then

$$\Delta p = \sigma \left(\frac{1}{R} - \frac{1}{y} \right) \quad (1)$$

From geometry it follows, if r is the radius of the spheres, that

$$\frac{1}{R} = \frac{2(r-y)}{y^2} \quad (2)$$

and accordingly,

$$y = \frac{-3 + (9 + 8r\Delta p/\sigma)^{1/2}}{2\Delta p/\sigma} \quad (3)$$

Putting $y/r = k$ and $R/r = \alpha$, the volume v of the ring of liquid is readily found to be

$$v = 2\pi r^3 \frac{\alpha}{1+\alpha} f(k, \alpha) \quad (4)$$

Fig. 1. Capillary ring of liquid between two spheres.

where

$$f(k, \alpha) = (k + \alpha)^2 - \alpha(k + \alpha) \left\{ 1 - \frac{1}{(1 + \alpha)^2} \right\}^{1/2} \\ - \alpha(k + \alpha)(1 + \alpha) \sin^{-1} \frac{1}{1 + \alpha} + \alpha^2 - \frac{\alpha}{1 + \alpha}.$$

This gives the volume of a single ring formed at a contact of two spheres in terms of parameters involving the quantity Δp which will be given consideration later.

In an earlier paper¹ the writers showed that in the natural piling of uniform spheres to a porosity P , the average number n of contacts per sphere is given by the approximate relation

¹ Smith, Foote and Busang, Phys. Rev. **34**, 1271-1274 (1929).

$$n = 6 \frac{1 + 1.828x}{1 + 0.414x} \quad (5)$$

where

$$x = (0.476 - P)/0.217$$

The number N of spheres per unit volume is

$$N = \frac{1 - P}{4\pi r^{3/3}} \quad (6)$$

Fig. 2. Schematic diagram of drainage experiments in which the meniscus surface is above the free surface by the distance h equal to the capillary rise.

Since in the complete assemblage, two spheres determine a single contact, the number of contacts per unit volume is $Nn/2$ and the volume V of liquid retained per unit volume of packed space is

$$V = Nnv/2. \quad (7)$$

The value of Δp depends upon the manner in which drainage occurs. In general the flow of fluid through any single pore composed of three adjacent grains is along the axis normal to the plane of the grain centers, as is the case with a meniscus falling in a simple cylindrical tube. The interface always drops in a direction parallel to the axis of the tube provided that it is not too large. Let us consider a single contact and the pores on either side. As the complex meniscus of the whole sand body falls, the portion of it in this restricted region drops through the adjacent pore spaces wrapping itself around the contact point. As the interface falls further the liquid immediately under the contact point is constricted and finally breaks, leaving that around the contact in the form of a ring and separated from the main body

of liquid. The final curvatures of the ring are closely equal to those which it had just prior to breaking and these are determined by the pressure difference Δp prevailing at that instant, subject, of course, to the limitation that the spheres are not too large.

The simplest case is that in which Δp is the meniscus pressure drop prevailing at maximum capillary rise, a condition which can be produced by allowing the free liquid and meniscus to fall simultaneously and very slowly in a U-arrangement such as is shown in Fig. 2. *A* contains the grains and *B* provides the liquid receptacle and is connected to *A* by a small tube *C*. If now the liquid is allowed to drain from the system by bleeding it from the stop-cock, the meniscus will remain at a height *h* above the free liquid in *B* which will not differ greatly from normal capillary rise provided the drainage takes place sufficiently slowly. The pressure drop Δp across the meniscus formed by the liquid surface within the sphere assemblage is accordingly given by the capillary equation

$$\Delta p = \sigma \left(\frac{1}{r_1} + \frac{1}{r_2} \right) = \rho g h \quad (8)$$

where r_1 and r_2 are the principal radii of curvature of an element of the meniscus, ρ the density of the liquid, g the acceleration of gravity, and h the height of capillary rise for the particular element. In a paper on "Capillary Rise of Liquids in Homogeneous Sands," to appear later, the writers show that when h is large the average value of $\rho g h$ over the entire meniscus is given by the approximate relation:

$$\overline{\rho g h} = \frac{2\sigma}{r} \left(\frac{0.651 + 0.256x}{0.349 - 0.256x} \right) \quad (9)$$

From Eqs. (3), (8), and (9), we find

$$k = \frac{y}{r} = \frac{-3 + (9 + 8A)^{1/2}}{2A} \quad (10)$$

where

$$A = 2 \left(\frac{0.651 + 0.256x}{0.349 - 0.256x} \right)$$

and from Eqs. (2) and (10)

$$\alpha = k/(Ak + 1) \quad (11)$$

The Eqs. (10) and (11) determine α and k from which v can be calculated by substitution in Eq. (4).

It will be observed that retention of this type is independent of the density, surface tension and viscosity of the particular liquid used. No dependence on viscosity, of course, is to be expected because of the very slow rate of drainage. Also the retention per unit volume of packed space is inde-

pendent of the radius of the spheres used, being a function of the porosity alone as can be seen by substitution of Eqs. (4) and (6) in Eq. (7) from which we obtain

$$V = \frac{3}{4}n(1 - P)\frac{\alpha}{1 + \alpha}f(k, \alpha). \quad (12)$$

Fig. 3 shows the volume V of retained liquid per unit volume of packed space as a function of the porosity and is plotted from Eq. (12). A curve of this type is to be expected. While the number of contacts increases as we decrease the porosity, the height of capillary rise increases as do also the resulting ring curvatures. Hence the volume of a single ring must decrease with decreasing porosity, offsetting the increased number of contacts.

Fig. 3. Volume of retained liquid per unit volume of packed space as a function of porosity.

An experimental investigation was undertaken to test the validity of Eq. (12). The arrangement used is shown in Fig. 4. In principle it is a duplication of that shown in Fig. 2. A , C and D are spherical reservoirs each enclosing a volume of about two liters. A wire gauze was placed at the bottom of A in which the spherical grains were packed. C and D respectively served to fill and collect the liquid whose retention was to be investigated. B , a 3 cm cylindrical glass tube was used as a free liquid container during capillary drainage. a , b and c denote stop cocks for closing off the principal reservoirs. f and g are ground glass stoppers each provided with a small capillary to prevent excessive loss of liquid by evaporation, but permitting atmospheric pressure to prevail.

The procedure was to fill the flask *C* and weigh it. It was then placed in connection with the free liquid reservoir *B* by means of a large ground glass stopper *d*. With stop-cocks *a* and *c* open and *b* closed, the liquid was allowed to slowly fill *A* to the top of the grains. Valve *a* was then closed and the surplus liquid in *C* drained into the flask *D*, connected to the system *A* - *B* by a ground glass stopper *e*. The valve *b* was closed so that initially *B* was completely filled. Valve *b* was now opened a little and the liquid in the U-system *A* - *B* allowed to drop sufficiently slowly to keep capillary equili-

Fig. 4. Arrangement of apparatus in drainage experiments.

brum preserved. The surplus liquid was collected in *D* and weighed. That which remained in *A* was calculated from the difference in weights of liquid drained from *C* and into *D*.

With the smaller sizes the drainage time was necessarily longer, with a consequent increase in experimental losses. For this reason the retention of glass pearls and sands, was determined by taking small samples of about 100 grams each from the grain reservoir immediately after drainage. These were quickly weighed, dried in an oven at 80°C and reweighed, the difference being the weight of the retained liquid. Lead shot of radii 0.219 cm and 0.165 respectively as well as glass pearls of radii 0.0316 cm and standard Ottawa silica sand of radius 0.0443 cm were used in conjunction with a series of liquids of different surface tension and viscosity, the former varying between 25 and 72.8 dynes/cm and the latter from 0.009 to 1.38 poises. Kerosene was used in the cases of glass pearls and sands owing to the impracticability of the methods when volatile liquids such as CCl_4 are used. Its viscosity is such as to permit drainage in a reasonable time. Table I

summarizes the results. The observed retentions in cm^3 of liquid per cm^3 of packed volume are listed in column 5 of the table. Column 6 gives the corresponding quantities computed from Eq. (12). The agreement in general is good.

	0.0443	0.359	Kerosene	.0292	.0222	.811	28.5

The results indicate that the wetting layer, a few molecules in thickness, is the only film present in assemblages of uniform spheres, and the volume of liquid so held is negligible in comparison with that found in the form of rings at the grain contacts. The quantities retained are obviously too large to be accounted for by the molecular forces involved in the formation of adsorbed films on a uniform surface. The shot and glass beads used had fairly uniform surfaces while the sand did not. Where rough surfaces are involved, small depressions filled with liquid can exist provided only that they are sufficiently deep to permit proper equilibrium curvatures. Such a type of surface film is permissible, and may account for the fact that the experimental values for sands are in excess of those calculated, although the lack of sphericity of the sand grains may be the controlling factor.

A REPRESENTATION OF THE DYNAMIC PROPERTIES
OF MOLECULES BY MECHANICAL MODELS

By C. F. KETTERING, L. W. SHUTTS AND D. H. ANDREWS

GENERAL MOTORS CORPORATION, RESEARCH LABORATORIES,¹ DETROIT, MICHIGAN.

(Received June 23, 1930)

ABSTRACT

Mechanical models have been constructed to represent the dynamical systems believed to exist in the molecule. Assuming that the intramolecular forces lie along lines associated with the chemical bonds and that for small vibrations they obey Hooke's law and have the mechanical character of spiral springs, it is possible to get a picture of the forces and masses which can be represented on a large scale by steel balls and spiral springs. Models have been constructed for some of the simpler non-polar molecules. They are found to have characteristic frequencies which correspond very closely to the frequencies observed in the Raman spectra, and it is possible by this means to identify the Raman lines with definite types of motion of particular atoms in the molecule. This substantiates the view that Raman lines correspond very closely to characteristic fundamental molecular frequencies.

INTRODUCTION

THIS paper describes an attempt to make some mechanical models of the dynamical systems of forces and masses which are found in real molecules. The possibility of doing this lies in the fact that according to optical and thermal data the smaller nonpolar molecules are dynamically rather simple.^{2,3} This simplicity is brought about in several ways. In the first place the only effective masses in the molecule are the nuclei of the atoms which may be regarded as point masses. The space relations of these masses to each other can be deduced to a large extent from the studies of the crystal lattice by means of x-rays. In the second place the forces in the molecule also appear to be simple in nature, lying for the most part along the lines which join the nuclei and which have been associated with the chemical bonds. In fact, the forces of the bonds are so much greater than any of the other forces acting on the atoms that they alone are of importance dynamically.

The problem is further simplified by the nature of the bond itself which behaves in a manner very analogous to a spiral spring. Thus for the small displacements with which we deal in studying the behavior of the molecule in the lowest vibrational levels we can see that the bond forces will obey

¹ The results reported here were arrived at largely as a development of the concepts of molecular structure originated by the senior author (C.F.K.). The success of the project is due chiefly to the cooperation of the many members of the laboratory staff who assisted in both the mechanical and physical part.

Hooke's law with regard to the extension or compression of the bond. There is, however another feature of the mechanical nature of the bond which has been largely neglected heretofore. The organic chemist in trying to explain the behavior of ring compounds has suggested that the bonds from a carbon atom will normally bear certain spatial relations to each other. This normal position has been generally accepted as that in which the bonds make the tetrahedral angle with adjoining bonds. In a cyclic compound such as a ring composed of four carbon atoms, it has been assumed that a strain is introduced by the alteration of the angles between the bonds. The concept has thus arisen that, in addition to elasticity of stretching, the bond has also elasticity of bending. This idea has been substantiated by recent data from the Raman spectra which show the force necessary to bend a bond is about one fifth that necessary to stretch it.

Data from the Raman and infrared spectra, as well as from specific heats,³ have also indicated another regularity in the nature of the bond which simplifies considerably the construction of a mechanical model. It is found that the restoring force due to the stretching of a normal nonpolar bond is always about the same whether the bond be between two hydrogens, a hydrogen and a carbon, two carbons, a carbon and an oxygen, or any other similar position. It thus would appear to be possible to represent all the bonds in a mechanical model by means of the same kind of spiral spring. If the ratio of the stretching force constant to the bending force constant were chosen correctly it should be possible to make a model which would quite closely represent the actual molecule.

Until recently the data have been quite incomplete from which one could find the fundamental mechanical frequency in a molecule. Developments^{3,4,5} in the study of the Raman spectra, however, indicate that the frequencies found there do correspond rather closely to real mechanical frequencies in the molecule. It therefore seems probable that if a mechanical model of a molecule were correctly constructed the characteristic frequencies found in it should correspond term by term to the frequencies observed in the Raman spectra. We should be able to get from a Raman frequency to a model frequency and *vice-versa* by multiplying or dividing by the proper constant which depends on the ratio of the mass of the molecule to the mass of the model, and of the force of the chemical bond to the force of the spring which represents it.

THE CONSTRUCTION OF THE MODEL

The first problem in constructing the model was the determination of the ratio of the stretching to the bending force in the spring which was to be used to represent the chemical bond. In order to simplify the problem it was decided to omit the hydrogen atoms from the first series of models, thus representing only the atoms of atomic weight of twelve or greater. The hydrogens, being so light, have almost no appreciable energy at ordinary tempera-

⁵ A. S. Ganesan and S. Venkateswaran, *Indian Journal of Physics* 4, 195 (1929).

tures, and contribute very little to the dynamical character of the system. We were thus left with the problem of determining the nature of the bond between two atoms like carbon, oxygen, or chlorine.

We have a direct indication of the strength of the carbon-carbon bond in the Raman spectrum of ethane. There is one line at 990 wave numbers which with very little doubt corresponds to the frequency of vibration of the two carbon atoms. By means of the formula,

$$\nu = \frac{1}{2\pi} \left(\frac{k}{m} \right)^{1/2} \quad (1)$$

where ν is the frequency, m is the reduced mass of the system, and k is the force constant, we can calculate what the stretching force for the carbon-carbon bond will be. It turns out to be about 4×10^5 dynes per cm. Methyl alcohol which is dynamically similar to ethane gives a similar value for the force.

Fig. 1a.

The calculation of the bending force is quite a bit more uncertain as it is only involved when we have at least three atoms in the molecule. From the study of ethyl alcohol and benzene and its derivatives, the value of 0.66×10^5 dynes per cm has been calculated by defining the bending force as a force necessary to displace an atom in a direction perpendicular to the bond joining it to another atom which is held stationary. While this concept of the bending force may seem somewhat arbitrary, it would appear to be the best means of approach available at the time. A better knowledge of just what it is can probably be obtained as our knowledge of molecular dynamics increases.

From a consideration of these values, a helical spring to represent the bond was decided upon. It has the following characteristics:

Mean Diameter of Coil	13/16 in.
Diameter of wire	#11 (0.120)
No. of active turns	10
Free length	2-1/2 in.
Force per inch deflection	53 lbs.

The actual weight of the spring when completed was $1\frac{1}{2}$ ounces. Steel balls $1\frac{1}{8}$ in. diameter weighing 0.2 lbs. each were used to represent the carbon atoms. To obtain the desired value for the bending of the spring, the distance between the centers of the balls was set at $3\frac{3}{4}$ in. Some of the models constructed in these proportions are shown in Fig. 1a.

METHOD OF STUDY

In order to study the fundamental vibration frequencies of such models, it is necessary to activate them by means of vibrational impulses of various frequencies. This was successfully accomplished by using a rubber band to attach one of the balls to an oscillating arm having $\frac{1}{4}$ in. stroke. This arm was operated by a reciprocating yoke on an eccentric driven by a variable speed motor. The model was suspended on rubber bands in such a manner that the frequency of the natural period of the suspension was much lower than the lowest period in the model.

Since the vibrations of the models covered a range of frequencies from 200 to 3500 cycles per minute, it was necessary to use some special means of observation in order to determine the characteristic motion of the various vibration periods. This was accomplished by illuminating the model with a neon lamp of a specially constructed stroboscope giving a large field of illumination. The circuit breaker of the stroboscope was geared to the activating motor shaft so that the neon lamp flashed at a frequency 2% slower than the exciting frequency applied to the model. Thus when the model was vibrating, a slow motion image, 1/50th of the actual frequency, was obtained. Thus at a frequency of 3000 cycles per minute, the model would appear to move through one cycle per second making it very easy to study the characteristics of the motion.

The tuning was found to be very sharp. When the motor was running at a speed which did not correspond to a characteristic frequency, the model was absolutely quiet. When the motor speed came within about five percent of a characteristic frequency, however, the balls began to move over the paths characteristic of that frequency and with closer tuning would generally vibrate with an amplitude of the order of $1/2$ in. This, of course, depends on the type of motion and the point of activation to some extent. The tuning was sharp enough, though, so that the characteristic frequencies could be determined to within two or three percent, and it was easy to see just what type of motion corresponded to that frequency.

There was little complication because of harmonics. One or two of the lowest frequencies would sometimes appear when the speed of the motor was double their fundamental value, but could easily be recognized as harmonic because the balls were vibrating with twice the frequency which they should have had for that motor speed. The amplitude of these harmonics was always small. There seemed to be a little trouble from spurious vibrations, that is, vibrations occurring because the springs actually had mass. These are called spurious because they would not be found in the real molecule where the

only mass is in the nuclei. They were easily recognized by studying the motion of the springs under the neon light.

The method of study consisted in activating the model starting with a frequency of about 100 r.p.m. and raising the motor speed continuously to the maximum of 3600. As the characteristic frequencies were reached, they would be recognized by the appearance of motion of the balls under the neon light and the frequencies of revolution would be tabulated as read from a tachometer connected to the motor shaft. After going through the range of frequencies, a further study would be made by approaching each frequency carefully from above and below and observing as accurately as possible the motions of the balls at that frequency. The same model would be vibrated at several different positions by attaching the activating rubber band in various ways. It was found that while this sometimes altered the amplitude of the various frequencies, their values and number remained the same. In this way we have secured data on the characteristic frequencies of models of a number of the commoner organic compounds. A discussion is given in detail in the following paragraphs.

RESULTS

MODELS WITHOUT HYDROGEN REPRESENTED

Benzene. Benzene was chosen as one of the compounds for study because of the uncertainty regarding its structure. Five different models of benzene, illustrated in Fig. 1a, were constructed as follows:

I. The Kekulé formula. The six balls representing the carbon atoms are arranged in a hexagon, and joined with alternate single and double bonds so placed that the tetrahedral angle is formed between any two adjoining bonds. The double bonds are made by putting two of the standard springs in parallel. The result is a "puckered" hexagon.

II. The Kekulé formula, plane. This is similar to model I except that the bonds are so arranged that the balls form a hexagon in a plane.

III. Centric formula. In this model the six balls are joined by single bonds into a "puckered" hexagon. There are in addition three cross bonds joining carbon atoms opposite each other in the ring. Each of these cross bonds is formed of a standard spring with a sufficient extension of wire on one end to give it the necessary length. In model IIIa the three cross bonds can slide over each other freely. In model IIIb they are clamped together in the center.

IV. Centric formula. This is the same as the preceding model except that the cross bond is formed by two standard springs joined together in the center. In IVa the bonds slide freely at the center and in IVb they are clamped together.

V. Centric formula. This is similar to the preceding model except that the bonds are so arranged that the six balls lie in a plane.

In order to compare the frequencies found in these models with the Raman spectra, it is necessary to calculate a conversion factor for passing from r.p.m.

to wave numbers. This conversion factor C may be expressed in terms of the masses and elastic constants by means of the equation

$$C = \frac{\nu \text{ r.p.m.}}{\bar{\nu}} = 60c \left(\frac{k_s m_m}{k_m m_b} \right)^{1/2} \quad (2)$$

where $\bar{\nu}$ is the frequency in wave nos., ν r.p.m. is the frequency in r.p.m., k_m is the elastic constant for the bond in the real molecule, k_s is the elastic constant of the spiral spring, m_b is the effective mass of the ball, m_m the mass of the nucleus, and c the velocity of light.

Fig. 1b. Models of benzene.

In the case of the fastest motion in benzene, the effective mass will be approximately that of a ball plus one and one-half springs. Of course this effective mass will be different for different types of vibration, but this seems to be sufficiently close approximation. Using the proper values, we find that C has a value of 3.1, which may be considered equal to three, within our limit of error.

The results of the study of these models are shown in Fig. 1b. The Raman spectrum for benzene is shown in the last line of the figure. The lines at 1500 cm^{-1} and at 3000 cm^{-1} (not shown) are almost surely due to the hydrogen which is not represented in this model. The four lines between 600 and 1200 cm^{-1} have been reported by almost everyone studying benzene and are known quite accurately. There seems to be also considerable evidence for a frequency in the neighborhood of 360 . A series of bands observed in the in-

frared^{6,7} indicate a fundamental frequency at 360 cm^{-1} and the specific heat⁸ of benzene also gives very strong evidence for a frequency in this neighborhood. These five frequencies then seem to be the characteristic frequencies due to the vibration of the carbon atoms in benzene.

As may be seen in Fig. 1b, the centric models are in fairly good agreement with the Raman spectrum. They show five fundamental frequencies of the type indicated in Fig. 2. These types of motion are also in agreement with those which had previously been assigned to benzene³ on the basis of its specific heat and Raman spectra. The degrees of freedom observed in the different types of motion add to give the correct number for the six carbon atoms, namely, twelve.*

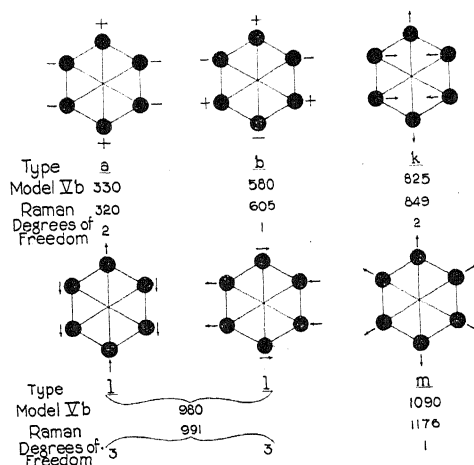

Fig. 2. Types of motion in benzene. + and - indicate motion out from and into plane of paper.

It is a little difficult to say just which model is in best agreement with the Raman spectrum. The evidence is perhaps a little in favor of *Vb*. This would be in accord with other observations which favor a plane hexagon for benzene. The double bond models, Kekulé formula, are distinctly different from the others in the higher frequencies. As may be seen in Table I, there is a frequency (*p*) which arises from a stretching of the single bonds. We would also expect a frequency (*q*) arising from a stretching of the double bonds. It was not possible with the present apparatus to excite this frequency because of the speed limitation of the motor, but calculation shows it would correspond to about 1540 cm^{-1} . As shown in the last column, there is fair agreement between these frequencies and the Raman frequencies at 1176 and 1592 cm^{-1} . It is true that we had assumed the latter to be close to a lateral motion of the

hydrogens, but this is not absolutely certain. We may conclude that there is some evidence in favor of the double bonded structure, but until we are a little more certain of the correct way to represent the double bond, too much weight must not be placed on this evidence.

Fig. 3. Models of toluene.

Toluene. The model for toluene is the same as model IV_b of benzene, with a ball and spring added to represent the methyl group. This group is attached so that it lies in the plane of the ring. The results are shown in Fig. 3. The addition of the methyl group causes a splitting of two of the frequencies which involve several degrees of freedom into doublets. Apparently one of the lines represents a motion which has its principal axis through the pair of carbon atoms in the ring which are in line with the methyl group, and the other two correspond to types of motion with the principal axis passing through the other two carbon atoms in the ring. This splitting may be seen by comparing the Raman spectra of benzene and toluene, and the model duplicates it almost exactly. There are also two low frequencies which represent the motion of the methyl group like a tail wagging. This interpretation has been verified by the heat capacity³ which shows a large value at low temperatures which must be due to the presence of low frequencies.

Carbon tetrachloride. In order to investigate the effect of changing mass in the model, a representation of carbon tetrachloride has been constructed, the chlorine atoms being balls, the weight of which bears the proper ratio to the standard ball which represents the carbon atom. The results are shown in Fig. 4. If we use the same conversion factor of three, there is a discrepancy between the model frequencies and the Raman frequencies. This seems to be due to the fact that the force constant for the carbon-chlorine bond is somewhat smaller than for the carbon-carbon. An arbitrary conversion constant was therefore used which was somewhat smaller than the other one. There is no frequency in the model for the Raman line at 452 cm^{-1} . It seems quite possible that this is a first harmonic of the line at 216 cm^{-1} .

Fig. 4. Models of chlorine compounds.

Chloroform. This is just like the model for carbon tetrachloride except that the one chlorine atom has been omitted. If the value of the conversion constant suitable for the carbon-chlorine bond is used, the lines are in fair agreement with the Raman spectra.

MODELS WITH HYDROGEN REPRESENTED

In order to make a model in which the frequencies of the hydrogens could be represented and could be observable with the means at our disposal, it was necessary to change the scale of the model. For convenience we used, to represent the hydrogen, the ball which had previously represented the carbon, and carbon was now represented by a ball of twelve times the mass of the small ball. A spring of the same wire and same number of turns as before was used to represent the bond. Its length was, however, shortened by a third because in the molecule the distance separating C-H is 1 \AA , while that separating C-C is 1.5 \AA . With this means, models were constructed and vibrated and the results are as follows:

Ethane. In the model of ethane it was found that there was one frequency corresponding to the vibration of the two carbon atoms with respect to each

other, also vibration of the hydrogen atoms at approximately three times the frequency of the carbon atoms. Of course, a new conversion constant must be used now that the mass has been changed. It might be calculated from the one previously adopted, but the difficulty of correcting for the mass of the springs makes this almost impossible. Since we are primarily interested in the ratio of the frequencies, it seemed wiser to adopt an arbitrary constant, and as it happens that in this model r.p.m. corresponds almost exactly to wave numbers, we have taken the conversion constant to be unity for the sake of simplicity.

As may be seen in Fig. 5, the ratio of the carbon frequencies (C-C) to the longitudinal hydrogen frequencies (H_L) is approximately that found in the Raman spectra for longitudinal vibrations. The model, however, shows transverse frequencies for the hydrogen (H_T) around 800 cm^{-1} . The line in the

Fig. 5. Models with hydrogen represented.

Raman spectrum which has been identified with this vibration lies at 1420 cm^{-1} . The reason for this discrepancy between the model and the spectrum is hard to explain. Apparently the force constant for lateral displacement of the hydrogen is quite a bit larger than the corresponding force in the carbon-carbon bond. We can not hope, of course, for a perfect representation of the real molecule, and it seems that we must be content here with having the number of frequencies correspond while the numerical value of this type of frequency lies considerably lower in the model than it does in the spectrum.

Ethylene. By putting a double bond between the carbon atoms, we shift the carbon-carbon frequency to about 1700 cm^{-1} . This corresponds to the shift observed in the Raman spectrum. The frequencies of the hydrogen are but slightly affected as the spectrum also shows.

Acetylene. Putting a triple bond between the carbon shifts the frequency to a little over 2000 cm^{-1} . This corresponds to the spectrum observed.

Methyl alcohol. Dynamically, this is quite akin to ethane. We find about the same frequency for the vibration of the two heavy atoms and the frequen-

cies in the same region for the vibration of the hydrogens as shown in Fig. 6. Again transverse vibrations of the hydrogens lie considerably lower than the lines ascribed to them in the Raman spectra.

It is very interesting to see the distinction between the two lines around 3000 cm^{-1} . When the model is vibrated at 2900 cm^{-1} the three hydrogens of the methyl group move in toward and out from the carbon while the hydrogen attached to the oxygen stays quiet. At 3000 cm^{-1} the three methyl hydrogens become quiet and the hydroxyl hydrogen vibrates. Since the masses and forces are the same in each case, this difference in frequency must be due to the fact that we have three balls reacting against the central ball in the one case and only one in the other case. It would, therefore, look as if the lines in the Raman spectrum could be positively identified with specific atoms in the molecule.

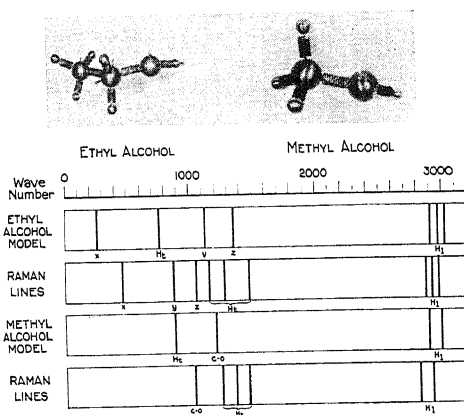

Fig. 6. Models with hydrogen represented.

Ethyl alcohol. This was constructed in the same way as the preceding models. We now have however, the possibility of three types of frequencies involving the large balls. The spectrum has the same general character as that of methyl alcohol. We now, however, find three lines around 3000 cm^{-1} . The lowest of these frequencies makes the three hydrogens in the methyl group vibrate while the others stand still. The next makes the two hydrogens in the CH_2 group vibrate, and the highest vibrates the hydrogen of the hydroxyl while the others remain quiet. We thus have a confirmation of the identification of these Raman lines with individual atoms. The transverse vibrations of the hydrogen again are lower than the lines identified with them in the Raman spectrum. The two upper vibrations (y , z) of the heavy atoms agree fairly well with the corresponding Raman lines. The lowest of the three (x) lies somewhat lower than the corresponding Raman line. This is probably due to the fact that in the model the mass is not distributed in space in the same way as in the molecule.

CONCLUSION

The general agreement which we have found between the characteristic frequencies of the models and the lines in the Raman spectra substantiates the character of the dynamical system in the molecule which we assumed in building the models. It seems reasonable to conclude that the molecular forces are directed along the lines associated with the chemical bonds and that mechanically, they are analogous to spiral springs. It appears also that the great majority of Raman lines have values of the frequency closely corresponding to fundamental mechanical frequencies in the molecule. Some of these frequencies are determined largely by the character of the whole molecule while others correspond to individual atoms or small groups of atoms. The mechanical model should prove very valuable in making these identifications and in ascertaining the structure of the molecule.

THE RELATION BETWEEN THE RAMAN SPECTRA AND
THE STRUCTURE OF ORGANIC MOLECULES

BY DONALD H. ANDREWS

CHEMISTRY LABORATORY, JOHNS HOPKINS UNIVERSITY

(Received June 23, 1930)

ABSTRACT

The following procedure is proposed for identifying the type of vibration in the molecule to which an observed frequency in a Raman spectrum corresponds. It is assumed that the only forces acting between the atoms in the molecule are those produced by the chemical bonds, and that there is a restoring force if the bond is stretched or if the angle which the bond makes with the other bonds on an atom is altered from the normal equilibrium value. It is also assumed that all non-polar chemical bonds have the same force constants in organic compounds. The different frequencies observed in the Raman spectra may then be considered as due solely to the variation in mass of the atoms concerned and to their space relation to each other, that is, whether they are in a straight chain, a branching chain, a ring, etc. It is possible to calculate in this way the number of Raman lines which should be observed for any compound, and the frequencies they should have. There is fair agreement with the observed spectra close enough so that the lines can be identified with different types of motion in the molecule.

INTRODUCTION

IN SPITE of the great deal of work which has been done on the Raman effect since its discovery two years ago we still lack a theory which is satisfactory for explaining at all completely the relation between the structure of organic molecules and the frequencies in the light which they scatter. The simplest explanation is that the shift in the frequency of the scattered light corresponds to a fundamental mechanical frequency in the vibrating molecule. This hypothesis has been supported by the extensive work of Dadiou and Kohlrausch¹ who have measured the Raman spectra for a large number of compounds, and have pointed out a great many significant relations between Raman lines and molecular structure in their own results and those of others working in this field. For example, certain special groups in a molecule such as hydrogen bound to carbon or two carbons bound by a double bond appear to have lines of definite frequency associated with them. Moreover, the calculation of the binding force between the atoms from the values of the Raman shifts lead to such uniform values among a wide variety of compounds that it seems reasonable to suppose that the frequencies of the Raman shift must correspond very closely to fundamental frequencies in the molecule.

Now, this hypothesis would also lead us to expect a close correspondence

¹ A. Dadiou and K. W. F. Kohlrausch: *Phys. Zeits.* **30**, 384 (1929); *Berichte d. deutschen chem. ges.* **63**, II, 251 (1930); *Wiener Berichte* IIa, **138**, 41, 336, 420, 607, 635, 799 (1929); **139**, 77 (1930).

between the frequencies of the Raman shifts and the frequencies in infrared absorption spectra. This has not been found to be true, particularly where the infrared absorption spectra can be interpreted with some degree of assurance, as in the simplest diatomic and triatomic molecules. However, Langer and Meggers² pointed out that in order to have such correspondence there must be a certain amount of freedom in the selection rules such as may not be found in triatomic or smaller molecules, but which may well be present in the case of molecules of more than six atoms, the class into which most organic compounds fall.

Granting that such a correspondence exists, the problem is still larger than merely finding relations between certain lines and certain characteristic groups in the molecule if we are to explain Raman spectra at all completely. Considering the mechanical nature of the vibrating system which we find in the molecule, it becomes evident that the majority of frequencies correspond to types of motion in which the whole molecule takes part rather than individual groups of two atoms. Now the problem of the dependence of frequencies on individual pairs of atoms as contrasted with the molecule as a whole is a moot question. Ellis³ and Marton⁴ have shown that certain band series in the infrared seem to be characteristic of pairs of molecules, and relatively independent of the structure of the molecule in which the pair is located. It appears, however, that this condition occurs only in special cases. For instance it may be due to the difference in mass of the vibrating particles. Thus in the case of hydrogen attached to carbon, we may expect the frequency ν , to be given rather closely by the equation for the harmonic oscillator

$$\nu = \frac{1}{2\pi} \left(\frac{k}{\mu} \right)^{1/2} \quad (1)$$

where k is the elastic constant of the C-H bond, and μ the reduced mass, determined by the equation

$$\frac{1}{\mu} = \frac{1}{m_1} + \frac{1}{m_2}$$

where m_1 is the mass of the hydrogen atom and m_2 the effective mass of the rest of the molecule. Since the ratio of m_2 to m_1 will nearly always be greater than twelve, it may be seen that the effect of the mass or structure of the rest of the molecule on the frequency will be small. Again this effect may be due to a pair of atoms being very tightly bound to each other and loosely bound to the rest of the molecule. An example of this is the $-\text{C}=\text{O}$ group which will be discussed later. On the other hand the majority of the frequencies will not depend on a pair of atoms, but on the nature of the molecule as a whole. This point is well brought out in Dennison's very complete analysis of the frequencies in me-

thane.⁵ It is therefore, evident that if we are to explain the general nature of Raman spectra, we must formulate some ideas about the nature of the mechanical system in the molecule.

THE NATURE OF THE MECHANICAL SYSTEM IN THE MOLECULE

There appear to be a few simple postulates which give us a basis for a qualitative explanation of Raman spectra. They may be summarized as follows:

(1) The frequencies of the Raman shifts correspond to characteristic fundamental mechanical frequencies in the molecule.

(2) The masses in this vibrating mechanical system are the nuclei arranged in space as indicated by the x-ray studies of crystal structure and by the deductions from organic chemistry.

(3) The forces under which these masses vibrate may to a first approximation be considered as acting along the lines associated with the chemical valence bonds. They can be characterized by two elastic constants, one of which, the stretching constant, gives the restoring force when two atoms are pulled apart unit distance from their equilibrium position in the molecule. The other, the bending constant, gives the restoring force when the angle is altered between the bonds joining a central atom to two other atoms.

(4) The amplitude of vibration will be so small compared with the equilibrium distance between the atoms that the variation of the force with distance will obey Hooke's law.

(5) The elastic constants for any type of bond are independent of the structure of the molecule in which it occurs, if there are no neighboring dipoles.

The reasonableness of the first postulate, at least for the cases we are considering, seems to be granted by those who have carried on the work in this field up to the present time. The second is self-evident. The third will perhaps seem more reasonable to those who have studied molecules from the chemical point of view than to those who are more familiar with their physical aspects. Nearly every chemist feels that the structural formulas of organic chemistry have met with such broad success in correlating chemical facts that the implications behind them must be given great weight. These formulas are based primarily on the assumption of the constancy of valence, one for hydrogen, two for oxygen, three for nitrogen and four for carbon; and on the hypothesis that the structure of a group or radical may remain unchanged throughout a complicated series of chemical reactions involving other parts of the molecule. In explaining the infrared spectra of methane Dennison⁵ postulated forces acting between the hydrogens which were stronger than the forces joining the hydrogens to the carbon. It might be possible to reconcile the existence of such forces with the behaviour of atoms in organic molecules, but it is certainly much simpler to think of the invariance of structure during chemical transformations as due to forces which act in the place where we have pictured the bond.

⁵ D. M. Dennison, *Astrophys. J.* **62**, 84 (1925).

If, however, we are to confine the forces which determine the structure of the molecule to the lines associated with chemical bonds we must say something more about the nature of the force than merely calling it attraction or repulsion. For example, there is considerable evidence that a long chain of atoms has a certain tendency to stay straight, and that there is resistance to bending. This idea has been made use of in organic chemistry by postulating that the normal position for the four valences around the carbon atom is at the tetrahedral angle. It is found that when closed rings of less than five carbon atoms are made, where the angle between the valences is less than 109° , there is instability and a tendency for the ring to break. This was pointed out by Baeyer in his "strain theory" of the organic ring compounds. It has also been evident from the observations on the specific heats of organic compounds that there must be thermal vibrations which involve bending of the molecule. This has been pointed out by E. O. Salant⁶ and by the author⁷ who attempted a calculation of the force constants from specific heat data.⁸ Ellis has suggested that the 6.2μ band attributed to the C-H group is due to this type of vibration.⁹ In a diatomic molecule this characteristic of the forces would not of course come into play since the motion of the two atoms would have to be merely toward and away from each other in order to preserve the conservation of momentum. However, in a triatomic molecule we can expect a type of motion in which there is a variation of the angle between the lines joining the two outside atoms to the central atom, and in such a case it is possible to define the forces acting in terms of the increased separation of the atoms, stretching, and of the variation of the angle, bending.

The justification of the fourth postulate may be seen in a calculation of the energy of most of these compounds at room temperature. It is found that for nearly all types of motion the molecules are in the zero vibrational level. The transition which causes the Raman shift appears to be from the zero to the first vibrational state in nearly all cases. For vibrations of this amplitude we may expect the forces to obey Hooke's law, and we can therefore expect that the motion will be that of a harmonic oscillator. The frequency will be related to the force and mass by Eq. (1).

The fifth postulate states that the strength of the bond for small amplitudes of vibration depends only on the two atoms which it connects, and is relatively independent of the structure of the rest of the molecule. The strongest support for this lies in the constancy of the characteristic frequencies for such bonds as C-H, C=C, and C=O throughout extensive series of compounds. This has been clearly demonstrated in the results of a number of authors,¹ particularly Dadieu and Kohlrausch.¹ In fact it had been rec-

⁹ J. W. Ellis, *Jour. Franklin Inst.* **208**, 517 (1929).

ognized on the basis of infrared spectra and specific heat data that the non-polar bond joining together atoms of H, C, O or N has nearly always the same elastic constant. For the stretching¹¹ of the bond the value is generally about 4×10^5 dynes per cm. The latest values for the elastic constants of various bonds are tabulated by Dadiou and Kohlrausch¹ where it may be seen how remarkably uniform these values are.

MOLECULAR STRUCTURE AND RAMAN SPECTRA

These five postulates permit us to draw some conclusions as to what we will expect to find in the Raman spectra. In the first place, as has already been pointed out, the frequency of the hydrogen atoms will be relatively independent of the structure of the molecule, and will appear as the fastest of all the frequencies since hydrogen is so much lighter than any of the other elements. On the other hand in compounds of heavy atoms such as chlorine

Fig. 1. Frequencies for three series of chlorine derivatives of methane, ethane and ethylene.

or bromine we will expect to find lines corresponding to much lower frequencies. Next with regard to the frequencies depending on the molecule as a whole we may say that the more complex the molecule, the lower the range of frequency, since a complex molecule will in general permit a kind of wave motion which will be of lower frequency than that for any pairs of atoms. By this effect frequencies may be secured which are as low as one tenth the value for a single pair of atoms, since the extension of the molecule into a chain may make possible very long wave length vibrations. On the other hand the frequency cannot be *increased* more than perhaps twenty percent

¹⁰ A. S. Ganesan and S. Venkateswaran, Indian Journal of Physics **4**, 195 (1929). A. Petrikaln and J. Hochberg, Zeits. f. Phys. Chem. **B3**, 217 (1929). P. Pringsheim and B. Rosen, Zeits. f. Physik **50**, 741 (1928).

by increasing complexity, since the number of forces acting on any one atom is limited to the number of valence bonds which it can possess. Thus, the only way of increasing the force acting on it is by introducing some strain, such as in ring formation and this effect is very small. With this in mind we may proceed to examine the frequencies which have been experimentally observed.

Lines associated with hydrogen. One of the earliest regularities to be pointed out in the Raman spectra was that of the lines in the neighborhood of 3000 cm^{-1} which appear to be due to the vibration of hydrogen attached to carbon. In Fig. 1 the frequencies have been plotted for three series of chlorine derivatives of methane, ethane and ethylene, respectively. It may be seen that in all compounds where hydrogen is present we have lines in the 3000 cm^{-1} region, but that when hydrogen is no longer present as in carbon tetrachloride, hexachlorethane, and tetrachlor ethylene there are no frequencies in this region.

Fig. 2. Frequencies observed in a number of carbon compounds.

Further observation of these data, moreover, indicate that there is a region from about 1100 to 1600 cm^{-1} where this same regularity holds true. Now Dennison⁵ in his analysis of methane frequencies concluded that there would be two frequencies in this region, as shown by the dotted lines in Fig. 1, which correspond to motions of hydrogen of the type which we have called bending. It is a little surprising that no Raman frequencies were observed in the 1400 cm^{-1} region but this may be due to the difficulty of working with gases, or to the more rigid selection rules which we may expect to find in smaller molecules. Ellis⁹ also has suggested that the 6.2μ band in the infrared may be due to this type of motion. It therefore seems reasonable to say that we have in these two groups of frequencies, 3000 cm^{-1} and 1400 cm^{-1} , the frequencies of the two types of motion which we would expect the hydrogen atoms to have, namely stretching and bending. Granting

this, we may proceed to an explanation of the remaining lines outside these regions which may be due to the heavier atoms.

Carbon frequencies. Fig. 2 shows the frequencies observed in a number of carbon compounds. As is to be expected methane shows only frequencies in the region which we have associated with hydrogen. Passing to ethane, however, as is shown in Fig. 1, we have in addition to the lines around 1400 cm^{-1} and 3000 cm^{-1} a line at 1000 cm^{-1} and as has been concluded by others,¹ this appears to be the frequencies of two carbon atoms vibrating with respect to each other. The spectrum of methyl alcohol is very similar to this as we might expect since we have merely replaced a carbon by an oxygen atom.

If the frequencies in ethane at 1000 cm^{-1} are really due to the carbon-carbon vibration, we would expect it to shift when a single bond is replaced by a double bond. This is found to be true in the spectrum of ethylene in which the line at 1000 cm^{-1} disappears and the line at 1600 cm^{-1} appears.

There has always been considerable dispute among chemists as to whether a double bond is stronger or weaker than a single bond. This question has been ably discussed by Fajans¹² and the Raman frequencies substantiate

Fig. 3. Frequencies observed for a number of compounds containing triple bonds.

his conclusions. If we make use of Eq. 1 and calculate the elastic constant for these two frequencies, we find that the shift is that which would correspond approximately to the doubling of the elastic constant. This is an additional confirmation that we have identified the line correctly. Moreover if we examine compounds in which there are double bonds such as the $\text{C}=\text{O}$ bond in acetaldehyde and acetone we find frequencies in this region. Over twenty compounds have been examined by Dadieu and Kohlrausch¹ in which these frequencies due to the double bond appear. If we increase the strength of the binding still further by passing to the triple bond we find higher frequencies just as should be expected. Fig. 3 shows the frequencies observed for a number of compounds containing triple bonds.

This group of frequencies shows very well the way in which a frequency depending principally on the strength of one particular bond, in this case the triple bond, may also be influenced by the structure of the molecule.

¹² K. Fajans, Chem. Ber. 53, 643 (1920), 55, 2826 (1922).

If we regard these groups as of the type $X-C\equiv Y$ it may be seen that the frequency will depend on the linkage $X-C$ and on the mass of X as well as on $C\equiv Y$. Thus in acetylene, since the hydrogen, X , is light, the only effective force for this vibration is $C\equiv Y$, giving a frequency of about 1950 cm^{-1} . In compounds of the cyanide type, however, where X is a heavy atom the force $X-C$ also contributes to the vibration and we find the frequencies in the neighborhood of 2200 cm^{-1} . It is particularly interesting to note that in $KC\equiv N$ the frequency is again lower. It seems quite possible that this is due to the fact that the $K-C$ bond is presumably polar and much weaker than the $C-C$ bond.

Another interesting compound in this connection is allyl iso-thiocyanate where we have a carbon atom between two double bonds. Two double bonds so placed are as effective as a triple bond and we find a corresponding frequency.

Effect of increasing molecular complexities. Having identified the above lines which correspond to vibrations of pairs of atoms we may proceed to examine the frequencies which appear to be due to vibrations of the molecule as a whole. The simplest illustration of the effect of increasing the complexity may be seen by comparing methyl and ethyl alcohol. We may regard these as diatomic and triatomic molecules respectively since the hydrogens are so light that they do not affect appreciably the vibration of the heavy atoms. In methyl alcohol we have a single line at 1000 cm^{-1} due to the $C-O$ vibration, as would be expected for a diatomic molecule. In a triatomic molecule, however, we would expect three fundamental frequencies since the total number of degrees of freedom is nine and of these three will be translational, and three rotational for the molecule as a whole, leaving three for vibration. Now according to our postulates the effective forces joining the atoms will be the forces of the two chemical bonds, namely $C-C$ and $C-O$. For each of these bonds we will expect one restoring force if the bond is stretched and another restoring force if the angle between the two bonds is altered corresponding to a bending of the molecule. It is a little difficult to say off-hand what the relative values of these two forces will be but from the analogy of the stretching and bending frequencies for hydrogen attached to carbon, we may expect the bending force to be only about one-quarter as strong as the stretching force.

This particular case has been carefully investigated by Yates.¹³ He has assumed forces of this type and finds that there should result one comparatively low frequency corresponding to the bending of the molecule and two frequencies not far from that for the diatomic molecule. If we ascribe the three frequencies between 1200 and 1400 cm^{-1} in the ethyl alcohol spectrum to hydrogen, the three remaining lines are in good accord with Yates' calculation. The spectrum of acetaldehyde which may similarly be regarded as a triatomic molecule shows a close resemblance to that of ethyl alcohol as

¹³ Yates, The character of the elastic forces in the homopolar chemical bond. See succeeding article.

might be expected. If it is true that the line at 450 cm^{-1} corresponds to a bending of the molecule then the fact that this frequency becomes only slightly higher in passing from ethyl alcohol, $\text{C}-\text{C}-\text{O}$, to acetaldehyde, $\text{C}-\text{C}=\text{O}$ indicates that doubling the bond decreases the ease of bending only slightly. On the other hand the appearance of the line at 1600 cm^{-1} shows that the force involved in stretching has been greatly increased.

Passing to more complicated molecules, we now find low frequencies appearing presumably corresponding to the presence of wave motion involving more than three atoms. Moreover, the number of lines increases, and as we get to heptane we find a fairly even distribution of the lines from the hydrogen region down to the low frequencies. The experimental observation of these more complex compounds is somewhat difficult because of the tendency for fluorescence which gives a continuous background, masking many of the lines. A number of the lines are also of very low intensity so that the agreement between different observers for compounds of the complexity of heptane is rather poor. For that reason, it is dangerous to draw too definite conclusions. However, one or two points seem worth mentioning. Lewis¹⁴ in a study of the possible frequencies in compounds of this type points out that the frequencies should be fairly evenly distributed from the lowest, corresponding to the longest wave-length possible in the chain, up to the highest, corresponding to the vibration of a pair of atoms. Pentane and heptane have spectra in accord with this view. It also seems worth noticing that the number of lines below the hydrogen region, which we may take as ending at about 1100 cm^{-1} corresponds roughly to the number of degrees of freedom for internal vibration of the heavy atoms which would be calculated from the number of atoms present in the molecule. Thus for heptane we should have $(3 \times 7) - 6 = 15$. In the region below 1100 cm^{-1} where these frequencies should appear we find fifteen lines for heptane and twelve for pentane, but for octane there are only ten, so that the argument is hardly conclusive.

CONCLUSIONS

The way in which the above postulates accounts for the great majority of Raman lines may be seen from the following calculation. We take 5×10^5 and 0.6×10^5 dynes per cm for the stretching and bending constants respectively of the single non-polar bond. These are the best average values from the latest data and the actual values for the various bonds do not appear to deviate from these by more than ten per cent. We can then calculate the ranges in which frequencies should appear in the different compounds, from the atomic weights and number of bonds involved. The variation in frequencies between different compounds is thus considered to be due only to the variation in the masses of the atoms and in the number and position of the bonds. The stretching constant for a double bond is taken as twice that for a single bond, and for a triple bond, thrice.

¹⁴ A. B. Lewis, Coupled vibrations with applications to the specific heat and infrared spectra of crystals. P. 568, this issue.

The values of the frequency which would be expected for the vibration of pairs of atoms can be calculated quite simply with the help of Eq. (1). The results of these calculations have been summarized in Table I. The values for C-H, C-O, and C-N are in good agreement with the observed lines which have been attributed to these bonds.

The case of C_6H_5-Cl is not so clear. It has been difficult to say just which Raman line is due to the vibration of the Cl. However, a series has been observed in the infra-red by Ellis¹⁵ which appears to be due to this type of motion and its fundamental frequency agrees very well with that calculated here.

The C=C bond in ethylene has a frequency which is well accounted for if we take the elastic constant as twice that for the single bond. With the C=O bond, however, we find the frequency to be quite a bit higher. Here the carbon is also joined to two other carbon atoms and since these bonds probably make an angle of about 109° with the double bond we may say as

TABLE I.

Bond	Compound	μ	k	Frequency Calc.	Obs.
Stretching					
C-H	H_3C-CH_3	1.0	5×10^5 dynes/cm	2920 cm^{-1}	2950 ¹⁸

¹⁸ M. Daure, Compt. Rend. **188**, 1492 (1929).

a first approximation that the effective force acting on that side of the carbon atom will be about equal to a single bond. An approximate calculation then gives the frequency as 1790 cm^{-1} which accounts at least qualitatively for the increase in frequency over the value for ethylene.

In the same way we find that C \equiv C in acetylene has a frequency accounted for by thrice the value for the single bond while the $C_6H_5-C\equiv N$ frequency lies higher by about the amount we should expect from the addition of the extra bond to the carbon atom.

The calculation of the bending frequencies may be made most simply in the case of molecules like methane or carbontetrachloride. One of the types of motion with the slow frequency will be that where the central atom stands still and the outer atoms vibrate toward and away from each other in pairs without stretching the bonds. In other words, we have a pure type

¹⁵ Ellis, Phys. Rev. **28**, 25 (1926).

of bending motion. As a first approximation we can treat this by means of Eq. (1) since the motion of a pair of atoms will be the same as if they were directly joined by an elastic force. Giving the value of 0.6 dynes per cm to this effective force which we believe is brought about by the bending of the bonds, we find values as shown in the second part of Table I. The first agrees fairly well with the value ascribed by Dennison⁵ to this type of motion in methane. The second agrees with the slowest observed Raman frequency, and there is evidence that this frequency is the one associated with this type of motion in a study of molecular models to which reference will be made later.

The case of ethyl alcohol which is more complex has been treated by Yates.¹³ With these values in his equation we find 480 cm^{-1} for the frequency due to bending, in good agreement with the slowest observed Raman line.

The calculated frequencies are indicated in Fig. 1 by the vertical lines in the crosses at the top of the figure. The horizontal lines indicate roughly what we should expect from the modification of the frequency by additional bonds or chain formation. Thus, as we have seen in the case of $\text{C}=\text{O}$ the frequency is raised about five per cent by the addition of the two bonds on the left of the carbon. On the other hand by lengthening out the carbon chain as in pentane the original C-C frequency can in a sense be modified to perhaps a third of its value or less.

It may be seen that for the compounds, for which the Raman shift frequencies have been plotted in the figures, we find frequencies just in those ranges which we would expect according to the structure. This seems to be the best evidence we have that the postulates regarding the nature of the mechanical system in the molecule are reasonable and that the Raman frequency shifts do correspond to fundamental mechanical frequencies.

Considerable light has also been thrown on this problem by a study of mechanical models of molecules¹⁶ which was based on the ideas developed by C. F. Kettering on the nature of elasticity in molecules. The problem has also been discussed from several other points of view by Yates¹³ and Lewis¹⁴ to whose papers reference has already been made. The conclusions drawn from these different lines of approach to the problem seem to be in substantial agreement.

THE ELASTIC CHARACTER OF THE HOMOPOLAR
CHEMICAL BOND

BY ROBERT C. YATES

MATHEMATICS DEPARTMENT, JOHNS HOPKINS UNIVERSITY

(Received June 23, 1930)

ABSTRACT

An attempt is made to obtain frequencies of internal vibrations of some organic molecules by the consideration of certain mechanical systems.

The system of three particles is studied assuming the forces of restitution elastic. Certain proportionality constants are determined, using a representative compound, which characterize the single valence bond. Calculated wave-numbers for CO_2 , CS_2 , CH_2Cl_2 , $\text{C}_2\text{H}_5\text{OH}$ are compared with observed data from Raman spectra.

I. INTRODUCTION

THERE has been a recent impulse on the part of the physical chemist to determine precisely the character of the chemical bond that retains the atoms in mutual attraction in molecular structures of organic compounds. An attempt in this direction has been made¹ under the assumption that the valence bond is of spring-like nature and the forces set up by a displacement are elastic. Mechanical models of representative molecules have been constructed accordingly and experiments run to observe the fundamental modes of vibration.² The correlation between such observed frequencies and those obtained from the Raman spectra was found to be surprisingly good. This prompted the desire to look more closely into several types of systems and to set up the dynamical equations of motion yielding frequencies that might be compared with experiment.

II. STATEMENT OF THE PROBLEM

We shall thus be concerned with the small vibrations of a system of particles about a position of stable equilibrium under certain definite assumptions, these assumptions to be supported by the closeness of agreement in the end.

The intramolecular forces that arise are set up by the mutual attraction and repulsion of the atoms, suggesting not only an elastic force between any two but also a force of restoration dependent on the angular divergence of neighboring bonds.

Definitely, it is assumed that the force tending to restore a particle after a displacement is the sum of two types of forces: the first acting along the

¹ D. H. Andrews, The Relation Between the Raman Spectra and the Molecular Structure of Organic Compounds, p. 544, this issue.

² F. Kettering, L. W. Shutts, D. H. Andrews, A Representation of the Dynamic Properties of Molecules by Mechanical Models, p. 531, this issue.

line of connection with another particle and proportional to the linear displacement (Hooke's law); the second acting at right angles to the first and proportional to the change in the angle between two adjoining bonds. This last may be restated as being proportional to the arc displacement.

We consider here only small displacements and higher order infinitesimals, in the presence of those of lower order, are neglected throughout. The motion of the particles is assumed to be in a given plane.

III. DETERMINATION OF THE FORCE CONSTANT k_1

Consider two particles of masses m_1 and m_2 constrained to linear motion. Assuming the force acting between them proportional to the displacement we find as is well known the frequency of vibration given by

$$\nu = (1/2\pi)(k_1/M)^{1/2} \quad (1)$$

where M denotes the relative mass $1/m_1 + 1/m_2$ and k_1 a factor of proportionality. If $m_1 = m_2 \equiv m$, we have

$$k_1 = 2\pi^2\nu^2m. \quad (2)$$

In order to evaluate k_1 we take the carbon-carbon combination of the diatomic molecule and assign the wave number of 1000 to motion along the line of connection.¹ This gives approximately $k_1 = 4 \times 10^5$ dynes per cm.

Before we may find a corresponding value for the remaining constant k_2 , that controls the restoring force arising from a change in the angle between neighboring bonds, we must look first at the system of three particles.

IV. THE SYSTEM OF THREE PARTICLES

Consider the system of three particles of masses m_1, m_2, m_3 , connected by two bonds as shown. We place the particles at the vertices of an isosceles triangle and select a reference frame with horizontal axis parallel to its base. These give the relations

$$\left. \begin{aligned} 2f/m_3 &= b/m_1 - c/m_2 \\ m_1d &= m_2a \end{aligned} \right\} \quad (3)$$

If the origin of coordinates be taken at the center of mass, we have

$$\left. \begin{aligned} f &= c - b \\ g &= a + d \end{aligned} \right\} \quad (4)$$

We introduce the notation:

$$\left. \begin{aligned} A &\equiv g/m_3 + a/m_1 \\ B &\equiv c/m_2 + f/m_3 = b/m_1 - f/m_3 \end{aligned} \right\} \quad (5)$$

so that $\tan \theta_2 = A/B$

Let the system be displaced to a position shown and let the components of displacement of the particles be $(1/m_i) \cdot (x_i, y_i)$.

The kinetic energy of the system is:

$$T = (\frac{1}{2}) [(\dot{x}_1^2 + \dot{y}_1^2)/m_1 + (\dot{x}_2^2 + \dot{y}_2^2)/m_2 + (\dot{x}_3^2 + \dot{y}_3^2)/m_3]. \quad (6)$$

The potential energy—dependent on the configuration—is composed of a potential V_1 due to linear displacement and V_2 due to rotation:

$$V_1 = (k_1/2)(\Delta d_1^2 + \Delta d_2^2) \quad (7)$$

$$V_2 = (k_2/2) \cdot \Delta S^2 = (k_2 d_1^2/2) \cdot \Delta \phi^2.$$

In order to find the explicit expressions for the quantities in (7) we obtain from the figure:

$$\left. \begin{aligned} d_1 \cdot \Delta d_1 &= -A(y_1/m_1 - y_3/m_3) + B(x_1/m_1 - x_3/m_3) \text{ etc.} \\ d_1^2 \cdot \Delta \phi &= d_1^2(\Delta \theta_1 - \Delta \theta_2) = A(x_1/m_1 - x_2/m_2) + B(y_1/m_1 + y_2/m_2 - 2y_3/m_3) \end{aligned} \right\} (8)$$

Fig. 1. System of three particles.

Since the resultant of the forces on the system is zero the center of mass will remain at rest in an inertial system. We may, therefore, write

$$\left. \begin{aligned} x_1 + x_2 + x_3 &= 0 \\ y_1 + y_2 + y_3 &= 0 \end{aligned} \right\} (9)$$

Furthermore the moment of the various forces about the origin is zero so that the angular momentum of the system about the origin is constant. Assuming that this angular momentum is zero, we have:

$$\begin{aligned} m_1 \begin{vmatrix} (b+x_1)/m_1 & -(a-y_1)/m_1 \\ \dot{x}_1/m_1 & \dot{y}_1/m_1 \end{vmatrix} + m_2 \begin{vmatrix} -(c-x_2)/m_2 & -(d-y_2)/m_2 \\ \dot{x}_2/m_2 & \dot{y}_2/m_2 \end{vmatrix} \\ + m_3 \begin{vmatrix} (f+x_3)/m_3 & (g+y_3)/m_3 \\ \dot{x}_3/m_3 & \dot{y}_3/m_3 \end{vmatrix} &= 0 \end{aligned} \quad (10)$$

which becomes on integrating:

$$By_2 = A(x_1 + x_2) + By_1. \quad (11)$$

The two energy functions may now be rewritten, because of the relations Eq. (9) and Eq. (11):

$$T = (\frac{1}{2}B^2) \{ [B^2/m_1 + A^2/m_2 + (A^2 + B^2)/m_3] \dot{x}_1^2 + (A^2 + B^2)(1/m_2 + 1/m_3) \dot{x}_2^2 + B^2(1/m_1 + 1/m_2 + 4/m_3) \dot{y}_1^2 + 2[A^2/m_2 + (A^2 + B^2)/m_3] \dot{x}_1 \dot{x}_2 + 2AB(1/m_2 + 2/m_3)(\dot{x}_1 + \dot{x}_2) \dot{y}_1 \} \quad (12)$$

$$V = (k_1/2d_1^2) \{ [(A^2 - B^2)/m_3 - B^2/m_1] x_1 + [(A^2 - B^2)/m_3] x_2 + AB(2/m_3 + 1/m_1) y_1 \}^2 + (k_1/2d_1^2) \{ [(A^2 + B^2)/m_3 + A^2/m_2] x_1 + (A^2 + B^2)(1/m_2 + 1/m_3) x_2 + AB(2/m_3 + 1/m_2) y_1 \}^2 + (k_2/2d_1^2) \{ AB(1/m_1 + 1/m_2 + 2/m_3) x_1 + (2AB/m_3) x_2 + B^2(1/m_1 + 1/m_2 + 4/m_3) y_1 \}^2. \quad (13)^*$$

These functions T and V must satisfy the Lagrangian equations of motion:

$$(d/dt)(\partial L/\partial \dot{x}_i) - (\partial L/\partial x_i) = 0 \quad (14)$$

where $L = T - V$. Inserting the expression L we have:

$$\begin{aligned} & [B^2/m_1 + A^2/m_2 + (A^2 + B^2)/m_3] \ddot{x}_1 + [A^2/m_2 + (A^2 + B^2)/m_3] \ddot{x}_2 + AB[2/m_3 + 1/m_2] \ddot{y}_1 = - (k_1/d_1^2) [(A^2 - B^2)/m_3 - B^2/m_1] \{ [(A^2 - B^2)/m_3 - B^2/m_1] x_1 + [(A^2 - B^2)/m_3] x_2 + AB[2/m_3 + 1/m_2] y_1 \} - (k_1/d_1^2) [(A^2 + B^2)/m_3 + A^2/m_2] \{ [(A^2 + B^2)/m_3 + A^2/m_2] x_1 + [A^2 + B^2][1/m_3 + 1/m_2] x_2 + AB[2/m_3 + 1/m_2] y_1 \} - (B^2 k_2/d_1^2) \cdot A \cdot [1/m_1 + 1/m_2 + 2/m_3] \{ A[1/m_1 + 1/m_2 + 2/m_3] x_1 + [2A/m_3] x_2 + B[1/m_1 + 1/m_2 + 4/m_3] y_1 \} \\ & [A^2/m_2 + (A^2 + B^2)/m_3] \ddot{x}_1 + (A^2 + B^2)[1/m_1 + 1/m_3] \ddot{x}_2 + AB[2/m_3 + 1/m_2] \ddot{y}_1 = - (k_1/d_1^2) [(A^2 - B^2)/m_3] \{ [(A^2 - B^2)/m_3 - B^2/m_1] x_1 + [(A^2 - B^2)/m_3] x_2 + AB[2/m_3 + 1/m_2] y_1 \} - (k_1/d_1^2) [A^2 + B^2][1/m_2 + 1/m_3] \{ [(A^2 + B^2)/m_3 + A^2/m_2] x_1 + (A^2 + B^2)[1/m_2 + 1/m_3] x_2 + AB[2/m_3 + 1/m_2] y_1 \} - (B^2 k_2/d_1^2)(2A/m_3) \{ A[1/m_1 + 1/m_2 + 2/m_3] x_1 + [2A/m_3] x_2 + B[1/m_1 + 1/m_2 + 4/m_3] y_1 \} \end{aligned} \quad (15)$$

$$\begin{aligned} & A[1/m_2 + 2/m_3] [\ddot{x}_1 + \ddot{x}_2] + B[1/m_1 + 1/m_2 + 4/m_3] \ddot{y}_1 = - (A k_1/d_1^2)(2/m_3 + 1/m_1) \{ [(A^2 - B^2)/m_3 - B^2/m_1] x_1 + [(A^2 - B^2)/m_3] x_2 + AB[2/m_3 + 1/m_2] y_1 \} - (A k_1/d_1^2)(2/m_3 + 1/m_2) \{ [(A^2 + B^2)/m_3 + A^2/m_2] x_1 + [A^2 + B^2][1/m_2 + 1/m_3] x_2 + AB[2/m_3 + 1/m_2] y_1 \} - (B^2 k_2/d_1^2)(1/m_1 + 1/m_2 + 4/m_3) \{ A[1/m_1 + 1/m_2 + 2/m_3] x_1 + [2A/m_3] x_2 + B[1/m_1 + 1/m_2 + 4/m_3] y_1 \}. \end{aligned} \quad (16)$$

These three Eqs. (15, 16, 17) define the motion of the system and are sufficient to determine the independent quantities x_1 , x_2 , y_1 .

* That the potential function as here written gives the correct forces is seen by calculating straight forwardly the forces acting on the separate particles. For example, the horizontal component of force acting on the first particle is $-(\delta V/\delta \cdot x_1/m_1)$.

On combining these we find:

$$\begin{aligned}
 & [B^2/m_1 + A^2/m_2 + 2B^2/m_3]\ddot{x}_1 + [(A^2 + B^2)/m_2 + 2B^2/m_3]\ddot{x}_2 + AB[1/m_2 - 1/m_1]\ddot{y}_1 \\
 & = (k_1/d_1^2) [(A^2 + B^2)/m_1 + 2B^2/m_3] \{ [(A^2 - B^2)/m_3 - B^2/m_1] x_1 \\
 & + [(A^2 - B^2)/m_3] x_2 + AB[2/m_3 + 1/m_1] y_1 \} - (k_1/d_1^2) [(A^2 + B^2)/m_2 \\
 & + 2B^2/m_3] \{ [A^2/m_2 + (A^2 + B^2)/m_3] x_1 + [A^2 + B^2][1/m_2 + 1/m_3] x_2 \\
 & + AB[2/m_3 + 1/m_2] y_1 \}
 \end{aligned} \quad (18)$$

which defines the particular type of motion that is unaffected by any bending of the bonds.

IV (B)

We now make the restriction that the two end particles be of the same mass, say $m_1 = m_2 \equiv m$. Eq. (18) becomes:

$$\begin{aligned}
 \ddot{x}_1 + \ddot{x}_2 & = - (k_1/d_1^2) [(A^2 + B^2)/m + 2B^2/m_3] (x_1 + x_2) \\
 & = - k_1(1/m + 2 \cos^2 \theta/m_3) (x_1 + x_2)
 \end{aligned} \quad (19)$$

where θ is a base angle (see table).

Thus the combined horizontal motion of the two end particles is simply harmonic. The third particle oscillates complementary to this.

Under this first restriction we solve Eqs. (15, 16, 17) explicitly for \ddot{x}_1 , \ddot{x}_2 , \ddot{y}_1 :

$$\begin{aligned}
 \ddot{x}_1 & = (k_1/d_1^2) \{ [(A^2 - B^2)/m_3 - B^2/m] x_1 + [(A^2 - B^2)/m_3] x_2 + AB[2/m_3 \\
 & + 1/m] y_1 \} - (2Ak_2/d_1^2) \{ A[1/m + 1/m_3] x_1 + [A/m_3] x_2 \\
 & + B[2/m_3 + 1/m] y_1 \} \\
 \ddot{x}_2 & = - (k_1/d_1^2) \{ [A^2/m + (A^2 + B^2)/m_3] x_1 + [A^2 + B^2][1/m + 1/m_3] x_2 \\
 & + AB[2/m_3 + 1/m] y_1 \} + (2Ak_2/d_1^2) \{ A[1/m + 1/m_3] x_1 + [A/m_3] x_2 \\
 & + B[2/m_3 + 1/m] y_1 \} \\
 \ddot{y}_1 & = - (Ak_1/d_1^2 B) \{ [(A^2 - B^2)/m_3 - B^2/m] x_1 + [(A^2 - B^2)/m_3] x_2 \\
 & + AB[2/m_3 + 1/m] y_1 \} - (2Bk_2/d_1^2) \{ A[1/m + 1/m_3] x_1 + [A/m_3] x_2 \\
 & + B[2/m_3 + 1/m] y_1 \}.
 \end{aligned} \quad (20)$$

If we are to find solutions of the type $x_i = C_i e^{\alpha t}$ for the differential equations (Eq. 20) we must require the vanishing of the determinant of coefficients:

$$\begin{vmatrix} \alpha^2 + a_{11} & a_{21} & a_{31} \\ a_{12} & \alpha^2 + a_{22} & a_{32} \\ a_{13} & a_{23} & \alpha^2 + a_{33} \end{vmatrix} = 0 \quad (21)$$

which is the characteristic equation—a cubic in α^2 —where the quantities a_{ij} are the constant coefficients that occur in the differential Eq. (20).

The determinant is readily reduced to:

$$\begin{vmatrix} \alpha^2 + b_{11} & 0 & 0 \\ a_{12} & \alpha^2 + b_{22} & a_{32} \\ a_{13} & b_{23} & \alpha^2 + a_{33} \end{vmatrix} = 0 \quad (22)$$

where

$$b_{11} = (k_1/d_1^2) [(A^2 + B^2)/m + 2B^2/m_3]$$

$$b_{22} = k_1 B^2/d_1^2 \cdot m + 2A^2 k_2/d_1^2 m$$

$$b_{23} = ABk_1/d_1^2 m - 2ABk_2/d_1^2 m$$

Solving Eq. (22) we get the two factors:

$$\alpha^2 + k_1(1/m + 2 \cos^2 \theta/m_3) = 0 \quad (23)$$

$$\alpha^4 + [(k_1 + 2k_2)/m + 2(k_1 \sin^2 \theta + 2k_2 \cos^2 \theta)/m_3] \alpha^2 + 2k_1 k_2 (2/m_3 + 1/m)/m = 0 \quad (24)$$

whose three roots $\alpha_1, \alpha_2, \alpha_3$, are pure imaginaries and we therefore write $\alpha_i^2 = -\mu_i^2$ from which we may obtain the normal fundamental frequencies of the system.

IV (c)

If all three particles were of the same mass, m , the foregoing expressions would simplify considerably. Under this restriction we rewrite Eq. (23):

$$\left. \begin{aligned} m\mu^2 - k_1(1 + 2 \cos^2 \theta) &= 0 \\ m^2\mu^4 - [(k_1 + 2k_2) + 2(k_1 \sin^2 \theta + 2k_2 \cos^2 \theta)]m\mu^2 + 6k_1 k_2 &= 0 \end{aligned} \right\} \quad (25)$$

The normal frequencies of this system are $\nu_i = (1/2\pi)\mu_i$ and the wave-numbers $\bar{\nu}$ are given by

$$\bar{\nu}_i = (\frac{1}{2})\nu_i \times 10^{-10} = \left(\frac{1}{6\pi}\right)\mu_i \times 10^{-10} \text{ cm}^{-1}. \quad (26)$$

V. DETERMINATION OF THE FORCE CONSTANT k_2

Referring to section III we proceed to calculate k_2 and for that purpose we select as most suitable a molecule of ethyl alcohol, the atoms arranged in groups as shown in the accompanying table.

We assume here that the bonds form the tetrahedral (approximately 109°) angle with each other in the position of rest. As an approximation, the atomic mass of the CH_2 group is taken as fourteen while the other two groups are assigned the average mass of sixteen. The mass of each group is supposed to be concentrated at the nucleus of each heavy atom. It is to be emphasized that there is no bond acting directly between the two end groups. We may thus apply Eqs. (25) of the preceding paragraph.

We find, on using the value of k_2 found in section III: $\bar{\nu}_1 = 1035$ as compared with the observed wave-number 1047.

TABLE I.

	Structure	Force Constants	Calculated			Observed		
			ν_1	ν_2	ν_3	ν_1	$\bar{\nu}_2$	ν_3
C_2H_5OH		$k_1=4$ $k_2=6$	1035	930	451	1047	884	450 ⁴
CO_2		$k_1=8$ $k_2=1.2$	1535	1320	703	3650	2350	683 ⁵
		$k_1=8$ $k_2=1.2$	1800	970	920			
		$k_1=32$ $k_2=4.8$	3600	1960	1820			
		$k_1=32$ $k_2=0.6$	3600	2817	978			
CS_2		$k_1=8$ $k_2=1.2$	1303	no value	no value	800	655	655 ⁴
		$k_1=4$ $k_2=6$	920	730	570			
CH_2Cl_2		$k_1=4$ $k_2=0.6$	917	1010	728	1151	715	283 ⁴
		$k_1=4$ $k_2=0.6$	1083	698	487			

⁴ A. S. Ganesan and S. Venkatesvaren, Indian Jour. Phys. 4, 195 (1929).⁵ R. H. Fowler, Statistical Mechanics, p. 64, Cambridge, 1929.

On using the other two fundamental wave-numbers 884 and 450 in the quadratic form (Eq. 23) we solve for k_2 , obtaining $k_2=0.6 \times 10^5$ dynes/cm as an average value. These values for the force constants had already been obtained in a very approximate manner from specific heats and Raman spectra.³

VI. SOME APPLICATIONS

We apply the results of the foregoing paragraphs to a few organic molecules, arranging the calculations in the accompanying table.

Carbon dioxide is definitely a double bonded structure and it was therefore supposed that the force constant k_1 would, in this case, be double its value for the single bond. It is found, however, that the values $k_1=32$; $k_2=0.6$ (or 1.2) dynes per cm gives results that best agree with experiment. The atomic arrangement is shown in table 2 under the heading "Structure," first with the bonds forming the tetrahedral angle and second with the atoms lying collinear. This last stable position seems to be most probable. The molecule of carbon disulphide gives best results if taken with the single bond. Dichlor methane not only seems to have a single bond structure but apparently has the straight line arrangement of its groups. Because of the agree-

³ D. H. Andrews Phys. Rev. 34, 1626 (1929).

ment between calculated and observed data in most of the cases considered it is fairly conclusive that the force constants as determined are quite valid. The percent of error is in itself not sufficient as an objection if it is considered that the frequencies might lie in the range of 100 to 10000 wave-numbers.

The writer is greatly indebted to Professor D. H. Andrews for suggesting the problem and to Professor F. D. Murnaghan for continued advice in the preparation of the paper.

STUDY OF THE SMALL VIBRATIONS OF SIX PARTICLES
IN A SYSTEM ANALOGOUS TO THE BENZENE
RING

BY ROBERT C. YATES

MATHEMATICS DEPARTMENT, JOHNS HOPKINS UNIVERSITY

(Received June 23, 1930)

ABSTRACT

The system of six particles is allowed to vibrate under certain restrictions, assuming an elastic nature for the restoring forces. Frequencies of vibration are obtained and compared with Raman data lending some support to the Claus construction of the benzene molecule.

INTRODUCTION

IN A previous paper¹ we have considered the small vibrations about a position of stable equilibrium of a system of three particles under the assumption that the forces set up by a displacement are elastic in character. It was definitely assumed that the restoring force was the sum of two types of forces; the first acting along the line of connection with another particle and proportional to the linear displacement; the second acting at right angles to the first and proportional to the change in the angle between two adjoining bonds. The results obtained for a few organic compounds pointed very strongly to the conclusion that two force constants $k_1 = 4 \times 10^5$ and $k_2 = 0.6 \times 10^5$ dynes per cm could be assigned as definite properties of the single valence bond which were independent of the particular molecule.

THEORY

In this paper we consider the system of six particles, (under the same assumptions as were taken for three particles), all of the same mass m lying in stable position at the vertices of a regular hexagon, whose side is of length a . Each particle has three connecting bonds as shown. If the angular momentum is zero and the center of gravity remains fixed, the system will have nine degrees of freedom. We, however, place certain restrictions on the motion of the system that will reduce considerably the order of the resulting characteristic determinant. The motion of the particles is assumed to be in a given plane and higher order infinitesimals, in the presence of those of lower order, are neglected throughout.

First we allow only motion along the 60 degree lines passing through the center of the hexagon. Let: (a) the displacement of the i^{th} particle from its position of rest be x_i ; (b) the change in the corresponding angles formed by the bonds be θ_i , and ϕ_i ; (c) the change in the length of the outside bonds be Δ_i . We have:

¹ R. C. Yates, The Elastic Character of the Homopolar Chemical Bond, p. 555, this issue.

$$\Delta_i = (x_i + x_{i+1})/2 \quad (i = 1, \dots, 6)$$

The energy functions are set up at once, following the procedure of the first paper:

$$\left. \begin{aligned} T &= (m/2) \cdot \sum_1^6 \dot{x}_i^2 \\ V &= (k_1/2) \cdot \sum_1^6 (\Delta_i^2 + x_i^2/2) + (a^2 k_2/2) \cdot \sum_1^6 (\theta_i^2 + 2\phi_i^2) \end{aligned} \right\} \quad (1)$$

If the center of mass is to remain fixed: $x_1 = x_4$, $x_2 = x_5$, $x_3 = x_6$, leaving three independent coordinates to fix the system.

Fig. 1. Vibration along radial lines.

From the figure $\phi_1 = (3^{1/2}/a)x_2$, $\phi_2 = (3^{1/2}/a)x_3$, etc. and since $\theta_1 = \phi_1 - \phi_6$ etc., we may write Eqs. (1) in the final form:

$$\left. \begin{aligned} T &= m \cdot \sum_1^3 \dot{x}_i^2 \\ V &= (k_1/2) (2 \sum_1^3 x_i^2 + x_1 x_2 + x_1 x_3 + x_2 x_3) \\ &\quad + 6k_2 \left(2 \sum_1^3 x_i^2 - x_1 x_2 - x_1 x_3 - x_2 x_3 \right) \end{aligned} \right\} \quad (2)$$

The equations of motion are accordingly:

$$\left. \begin{aligned} 2m\ddot{x}_1 &= -(k_1/2)(4x_1 + x_2 + x_3) - 6k_2(4x_1 - x_2 - x_3) \\ 2m\ddot{x}_2 &= -(k_1/2)(x_1 + 4x_2 + x_3) - 6k_2(-x_1 + 4x_2 - x_3) \\ 2m\ddot{x}_3 &= -(k_1/2)(x_1 + x_2 + 4x_3) - 6k_2(-x_1 - x_2 + 4x_3) \end{aligned} \right\} \quad (3)$$

On combining the Eqs. (3), we find the set of normal coordinates

$$z_1 = x_1 + x_2 + x_3 \quad z_2 = x_1 - x_2 \quad z_3 = x_2 - x_3$$

with resulting frequencies:

$$\left. \begin{aligned} \nu_1 &= \left(\frac{1}{2\pi} \right) [(3k_1 + 12k_2)/m]^{1/2} \\ \nu_2 = \nu_3 &= \left(\frac{1}{4\pi} \right) [(3k_1 + 60k_2)/m]^{1/2} \end{aligned} \right\} \quad (4)$$

Secondly, we restrict the system to motion on a circle of arbitrary radius $(a+b)$. We select a polar system of reference with pole at the mass center and initial line passing through a vertex of the hexagon.

Let: (a) the angular displacement of the particles be θ_i ; (b) the change in the angles between adjoining bonds be $\alpha_i, \beta_i, \phi_i$, where $\phi_i = \alpha_i + \beta_i$; (c) the change in the bond length be Δ_i .

Fig. 2. Vibration on a circle.

The energy functions are:

$$\left. \begin{aligned} T &= (m/2)(a+b)^2 \sum_1^6 \dot{\theta}_i^2 \\ V &= (k_1/2) \left[\sum_1^6 \Delta_i^2 + 3b^2 \right] + (a^2 k_2/2) \sum_1^6 (\alpha_i^2 + \beta_i^2 + \phi_i^2) \end{aligned} \right\} \quad (5)$$

From an inspection of the figure we find

$$\left. \begin{aligned} \alpha_1 &= (2\theta_6 - \theta_1 - \theta_4)/2 & \beta_1 &= -(2\theta_2 - \theta_1 - \theta_4)/2 \\ \alpha_2 &= (2\theta_1 - \theta_2 - \theta_5)/2 & \beta_2 &= -(2\theta_3 - \theta_2 - \theta_5)/2 \end{aligned} \right\} \quad (6)$$

etc. which give expressions for ϕ :

$$\phi_i = \phi_{i-1} - \phi_{i+1}. \quad (7)$$

In order to fix the center of gravity at the pole we must have

$$\left. \begin{aligned} \theta_5 &= \theta_1 + \theta_2 - \theta_4 \\ \theta_6 &= -\theta_1 + \theta_3 + \theta_4 \end{aligned} \right\} \quad (8)$$

If we now put angular momentum about the center of mass equal to zero we obtain the further relation $\sum_1^6 \dot{\theta}_i = 0$. We thus eliminate θ_4 , θ_5 , and θ_6 by means of the equations:

$$\left. \begin{aligned} \theta_4 &= -\theta_1 - 2\theta_2 - 2\theta_3 \\ \theta_5 &= 2\theta_1 + 3\theta_2 + 2\theta_3 \\ \theta_6 &= -2\theta_1 - 2\theta_2 - \theta_3 \end{aligned} \right\} \quad (9)$$

We obtain now also from the figure

$$\left. \begin{aligned} \Delta_1 &= b + [a(3)^{1/2}/2](\theta_2 - \theta_1) & \Delta_4 &= b + [a(3)^{1/2}/2](3\theta_1 + 5\theta_2 + 4\theta_3) \\ \Delta_2 &= b + [a(3)^{1/2}/2](\theta_3 - \theta_2) & \Delta_5 &= b - [a(3)^{1/2}/2](4\theta_1 + 5\theta_2 + 3\theta_3) \\ \Delta_3 &= b - [a(3)^{1/2}/2](\theta_1 + 2\theta_2 + 3\theta_3) & \Delta_6 &= b + [a(3)^{1/2}/2](3\theta_1 + 2\theta_2 + \theta_3) \end{aligned} \right\} \quad (10)$$

With the foregoing expressions we may rewrite Eqs. (5) explicitly in terms of the three remaining independent coordinates θ :

$$\left. \begin{aligned} T &= m(a+b)^2[5\dot{\theta}_1^2 + 9\dot{\theta}_2^2 + 5\dot{\theta}_3^2 + 12\dot{\theta}_1\dot{\theta}_2 + 8\dot{\theta}_1\dot{\theta}_3 + 12\dot{\theta}_2\dot{\theta}_3] \\ V &= (k_1/2)[9b^2 + (3a^2/2)(36\theta_1^2 + 60\theta_2^2 + 36\theta_3^2 + 84\theta_1\theta_2 + 60\theta_1\theta_3 + 84\theta_2\theta_3)] \\ &\quad + a^2k_2[24\theta_1^2 + 60\theta_2^2 + 24\theta_3^2 + 66\theta_1\theta_2 + 30\theta_1\theta_3 + 66\theta_2\theta_3] \end{aligned} \right\} \quad (11)$$

The corresponding equations of motion are:

$$\left. \begin{aligned} m(a+b)^2(5\ddot{\theta}_1 + 6\ddot{\theta}_2 + 4\ddot{\theta}_3) &= -\frac{(9a^2k_1/2)(6\theta_1 + 7\theta_2 + 6\theta_3)}{3a^2k_2(8\theta_1 + 11\theta_2 + 5\theta_3)} \\ m(a+b)^2(2\ddot{\theta}_1 + 3\ddot{\theta}_2 + 2\ddot{\theta}_3) &= -\frac{(3a^2k_1/2)(7\theta_1 + 10\theta_2 + 7\theta_3)}{a^2k_2(11\theta_1 + 20\theta_2 + 11\theta_3)} \\ m(a+b)^2(4\ddot{\theta}_1 + 6\ddot{\theta}_2 + 5\ddot{\theta}_3) &= -\frac{(9a^2k_1/2)(5\theta_1 + 7\theta_2 + 6\theta_3)}{3a^2k_2(5\theta_1 + 11\theta_2 + 8\theta_3)} \end{aligned} \right\} \quad (12)$$

If here we make the change of variables: $z_1 = 2\theta_1 + 3\theta_2 + \theta_3$, $z_2 = \theta_1 + 3\theta_2 + 2\theta_3$, $z_3 = \theta_1 - \theta_3$, the last set of equations may be replaced by:

$$m(a+b)^2\ddot{z}_i = -9a^2(k_1/2 + k_2)z_i \quad (i = 1, 2, 3). \quad (13)$$

The characteristic of the differential Eqs. (12) is degenerate and for this particular type of motion there is but one frequency:

$$\nu = [3a/2\pi(a+b)][(k_1 + 2k_2)/2m]^{1/2}.$$

CONCLUSION

If the hydrogens in the benzene ring are grouped with the carbons and if we assume bonds passing through the center of the hexagon we may apply our results. Using the values for the elastic constants which were secured in the previous paper² the values for the three characteristic frequencies are found, as shown in Table I.

TABLE I.

Force constants	ν Calculated	ν Observed ⁴
$k_1 = 4 \times 10^5$	—	605
	—	849
$k_2 = 0.6 \times 10^5$	—	991
	1145	1176
	1305	
	1750	—

The frequencies in the Raman spectra, believed to be associated with the carbon atoms, are also given. Now it has already been deduced from a study of the relation between Raman spectra³ that the experimentally observed frequency of 1176 cm^{-1} should correspond to the type of motion where all the carbon atoms move in and out together along the lines through the center of the hexagon. The agreement between this value and the calculated one of 1145 cm^{-1} substantiates this view and indicates that the values chosen for the elastic constants are fairly correct. The other two calculated frequencies fail to agree with any of those experimentally observed. It appears probable that for these the restrictions imposed on the motion were so far removed from the actual state of the molecule that these types of motion do not exist in actuality.

The writer's appreciation is due Professor D. H. Andrews for many valuable suggestions and Professor F. D. Murnaghan for constructive advice in preparing this paper.

COUPLED VIBRATIONS WITH APPLICATIONS TO THE
SPECIFIC HEAT AND INFRARED SPECTRA OF
CRYSTALS

BY ARTHUR B. LEWIS

THE JOHNS HOPKINS UNIVERSITY

(Received June 23, 1930)

ABSTRACT

The free periods of certain coupled systems of linear oscillators are considered in this paper. The complete system discussed consists of p identical, coupled, groups; each group containing n identical linear oscillators. The equations of motion of such a system lead to a determinantal equation of the pn^{th} order, of which the well-known determinantal equations of the uniformly loaded string and the finite wave filter are special cases. The solution of this general determinantal equation has been reduced to the solution of certain trigonometric equations. A solution for the free periods of the system is obtained for the case in which the coupling between the groups is small compared to the internal forces of the groups. In case only one or two groups are present the resulting equations can be solved readily to any desired degree of approximation for any values of the forces whatever. Certain special cases are noted in which, for special values of the forces, exact solutions become possible.

Sample calculations have been carried out which illustrate the behavior of the pn free periods of a system of pn particles when various forces act between the particles of the system, and when the pn particles are rearranged in various ways. With the aid of the equations obtained above the specific heats of four of the normal alcohols have been computed at low temperatures and compared with the experimentally determined values. A reasonable agreement is obtained between the observed and computed values, but with the data at hand the agreement cannot be said to be conclusive.

1. INTRODUCTION

RECENT investigators in the infrared spectra of organic compounds^{1,2} have attained considerable success in organizing their data by assigning certain prominent bands which are common to all organic compounds to certain modes of vibration between the component parts of the molecules under investigation. It is generally agreed that the strong band at about 3.5μ in the spectra of organic compounds is to be identified with the vibration of the hydrogen atom against the carbon atom. Similarly the band at about 28μ is to be identified with the vibration of carbon against carbon. This assumption of the spring-like nature of these chemical bonds is supported by several lines of evidence. The assignment of a characteristic frequency to a given bond permits the calculation of the force constant of the bond. This in turn leads to the calculation of the heat of linkage.³ There is good agree-

ment between the observed and computed values. Moreover these characteristic frequencies, when used in Einstein's formula,⁴ and Debye's formula,⁵ should give the specific heat curve of the compound at low temperatures. There seems to be reasonably good agreement between the computed curves and the observed values.⁶

It has therefore seemed worthwhile to consider a little more closely the free periods of vibration which one would expect from a mechanical model of one of these molecules, or from a group of molecules. To this end we shall consider the molecules under discussion as being represented by a series of massive particles attached at regular intervals to a massless elastic string. We shall first determine the free periods of a single group of massive particles, or of a single molecule, when various restrictions are placed on the ends of the molecule or group. We shall next consider the effect upon these periods of coupling two or more molecules or groups together, and shall thus determine the free periods of a system consisting of a number of identical molecules or groups coupled together. Such a system may be realized in the crystals of organic chain compounds. We shall finally be able to obtain the free periods of a single group of pn particles, and then to determine the effects produced on these frequencies by rearranging the pn component particles into various groupings (such as p groups of n particles each) keeping the total number of particles present always the same.

Mathematically we have here an extension of the problem of the vibration of a loaded string which has been treated by Lagrange,⁷ Lord Rayleigh,⁸ and others. The second order differential equations which arise from this problem are similar to those which arise in the solutions of the modes of vibration of other systems, particularly in the solution of wave filter problems. The analogous electrical case of the finite wave filter has been treated by Pupin,⁹ Campbell,¹⁰ Carson,¹¹ Wheeler and Murnaghan,¹² and others.

The method of solution consists, as usual, in setting up the differential equations of motion, which can be solved for periodic vibrations if a certain algebraic equation equals zero. This equation is known as the secular or characteristic equation. The roots of this equation give the frequencies of the free vibrations. In what follows we shall limit ourselves to motion in one dimension. In general, under these conditions, a system of N particles will possess N frequencies. If the system is free to move as a whole, or to rotate uniformly, the corresponding frequency is zero.

The system of particles which we shall discuss is obtained by arranging

pn equal particles into p groups of n particles each. We now introduce a small quantity, d , which we call the "coupling coefficient" and which measures the ratio of the force acting between the groups to the force inside of the group. An inspection of Fig. 1 will indicate that when $d=1$ the forces acting between the groups are the same as the forces acting within the groups, there is not longer any distinction between "groups," and we have the elementary case of the uniformly loaded string. The situation existing when $d=0$ must be examined with a little more care since d is defined as the ratio of two quantities. If d vanishes due to the fact that the internal forces present in each group are infinite we must say that we no longer have any vibrating group structure present. Our system will therefore vibrate as a uniformly loaded string of p particles, each of mass nm , the force constant of the string being that of the inter-group force. We have present the p frequencies characteristic of these p groups, while the other $p(n-1)$ internal frequencies

Fig. 1.

have been shifted to infinity. On the other hand if d vanishes due to the fact that the force between the groups has become infinitely small we must say that we have p groups present as before, but each infinitely removed from its neighbors and therefore entirely unaffected by them. We shall therefore expect the pn free periods of such a system to be the n free periods of a single group of n particles with free ends, each free period being repeated p times. These n frequencies characteristic of a single group of n particles with free ends will consist of one frequency, $\nu=0$, which corresponds to the vibration. When d has become small, but both forces remain finite, we can predict in a general way the behavior of the free periods. The p slowest vibrations will be slight modifications of the p vibrations which would be present if each group vibrated as a rigid whole, and on the other hand can be considered as corresponding to the p vibrations of frequency 0 for the p free molecules or groups. Similarly the $p(n-1)$ faster vibrations will be slight modifications of, and will therefore group themselves about, the $(n-1)$ internal vibrations which would be present if each group were entirely separated from its neighbors. While these, however, had been p -fold in the case of the independent molecules or groups, these p coinciding frequencies will be split up now into p separate components by the effect of the coupling.

II. STATEMENT OF THE MATHEMATICAL PROBLEM

Let us consider the motion of a massless, elastic string on which are fastened a number of massive particles of common mass " m ". Let these particles be arranged in identical and recurring groups of " n " particles, the common distance between particles of the same group being b . Let the distance between the n^{th} particle of any one group and the 1^{st} particle of the next group be a , there being p groups in all, see Fig. 1. Let the initial, uniform, tension in the string be T . Let us confine ourselves for the moment to small lateral displacements, all in the same plane, these displacements being so small that we may replace the sines of the angles by the angles themselves. This means that we can say, Fig. 1,

$$\sin \phi = \tan \phi = (y_r - y_{r-1})/a \text{ or } (y_r - y_{r-1})/b$$

We will so choose our axes that $y_0 = y_{pn+1} = 0$.

It is to be noted here that the introduction of the concept of an elastic spring under tension is a matter of convenience and not of necessity. In the same way we have restricted ourselves to small vertical displacements from convenience and not from necessity. We might have started equally well with a system of identical groups of particles in equilibrium under the influence of quasilastic restoring forces of any origin whatever. We have in this case to define a force constant which will be the restoring force per unit displacement acting on the r^{th} particle due to its displacement with respect to the $(r+1)^{\text{st}}$ or $(r-1)^{\text{st}}$ particle. This force constant we may call τ when the neighboring particle under consideration belongs to the same group as the r^{th} particle, and τ' when the neighboring particle under consideration does not belong to the same group as the r^{th} particle. The equations which will be obtained as Eqs. (1) will be found to follow immediately with the replacing of T/a and T/b by τ' and τ respectively. It will be noted in the following equations that the tension T always occurs in the expression T/a or T/b , which has the dimensions $F.L^{-1}$ as it should. It is apparent from what has been said that our coordinates y_r may be looked upon as generalized coordinates, the quantities which will occur in Eqs. (1) as $m\ddot{y}$ may be looked upon as generalized inertial forces, and the corresponding expressions such as $T/b(-y_{r-1} + 2y_r - y_{r+1})$ may be looked upon as generalized forces of restitution. The equations which will be obtained as Eqs. (1) are then equally capable of representing motions along the axis of X , perpendicular to the axis of X , rotations about this axis, or oscillations in properly coupled electrical circuits. The quantity defined as " d ", Eq. (3) will be given, in the light of the definitions of this paragraph as τ'/τ .

We can now write down the expressions for the kinetic and potential energy of the system,¹³ and set up the equations of motion by Lagrange's equations,

$$T - V = L$$

¹³ Partial Differential Equations of Mathematical Physics, Webster, p. 91, (1927).

The condition for a solution giving values for the C 's other than zero is that the determinant of the coefficients shall vanish. This gives a determinant of the pn^{th} order which we shall designate as F_p . It is to be understood by this notation that F_p represents the determinant of the pn^{th} order obtained from Eqs. (4) written for p identical groups of n particles each. We shall not be interested in this particular determinant when there are not exactly n particles in each group. The determinantal equation is

$$F_p = \begin{vmatrix} B-1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \dots & \dots & 0 & 0 \\ -1 & A & -1 & 0 & 0 & 0 & 0 & 0 & 0 & \dots & \dots & 0 & 0 \\ 0 & -1 & A-1 & 0 & 0 & 0 & 0 & 0 & 0 & \dots & \dots & 0 & 0 \\ 0 & 0 & -1 & B-d & 0 & 0 & 0 & 0 & 0 & \dots & \dots & 0 & 0 \\ 0 & 0 & 0 & -d & B-1 & 0 & 0 & 0 & 0 & \dots & \dots & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & A-1 & 0 & 0 & 0 & \dots & \dots & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & A-1 & 0 & 0 & \dots & \dots & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & B-d & \dots & \dots & \dots & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -d & B & \dots & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \end{vmatrix} = 0 \quad (5)$$

pn^{th}
order

For convenience the groups have been represented as having a limited number of terms, $n=4$.

This determinant is a function of the unknown $\lambda (=2\pi\nu^2$ where ν is the frequency) which is the variable entering through the quantities A and B . The solution of the problem will consist in finding those values of λ which will reduce the determinant to zero. A direct expansion of Eq. (5) will lead to an algebraic equation of the pn^{th} degree in λ . If it were possible to solve this algebraic equation, the resulting pn roots of λ would lead to the pn desired free periods of the system. This is the number of free periods which we expect from the number of degrees of freedom possessed by the system. Such a direct method of solution is not feasible in general. We must therefore look for transformations which will reduce Eq. (5) to a more tractable form. The general method of attack has been pointed out by Wheeler and Murnaghan.¹² The method consists essentially in reducing the expansion of Eq. (5) to a trigonometric equation in which the unknown, θ , is defined as a function of λ . The resulting trigonometric equation is well adapted to the processes of approximation.

An inspection of the determinant F_p will disclose that it is made up of certain simpler and recurring groups. As will be seen later the expansion of the complete determinant is obtained in terms of these sub-groups. We shall therefore define the following determinants:

$$D_n(d, d) = \begin{vmatrix} B & -1 & 0 & 0 & 0 \cdots & \cdots & 0 \\ -1 & A & -1 & 0 & 0 \cdots & \cdots & 0 \\ 0 & -1 & A & -1 & 0 \cdots & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 \cdots & \cdots & 0 & -1 & A & -1 & 0 \\ 0 & 0 \cdots & \cdots & 0 & 0 & -1 & A & -1 \\ 0 & 0 \cdots & \cdots & 0 & 0 & 0 & -1 & B \end{vmatrix} \quad (6)$$

n^{th}
order

$$D_n(1, d) = \begin{vmatrix} A & -1 & 0 & 0 \cdots & \cdots & 0 \\ -1 & A & -1 & 0 \cdots & \cdots & 0 \\ 0 & -1 & A & -1 \cdots & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 \cdots & \cdots & 0 & -1 & A & -1 & 0 \\ 0 & 0 \cdots & \cdots & 0 & 0 & -1 & A & -1 \\ 0 & 0 \cdots & \cdots & 0 & 0 & 0 & -1 & B \end{vmatrix} \quad (7)$$

n^{th} order.

$$D_n(1, 1) = \begin{vmatrix} A & -1 & 0 & 0 \cdots & \cdots & 0 \\ -1 & A & -1 & 0 \cdots & \cdots & 0 \\ 0 & -1 & A & -1 \cdots & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 \cdots & \cdots & 0 & -1 & A & -1 \\ 0 & 0 \cdots & \cdots & 0 & 0 & -1 & A \end{vmatrix} \quad (8)$$

n^{th} order

The determinant $D_n(1,1)$ is the determinant of the uniformly loaded string,¹³ and of the elementary wave filter.¹² The present notation has been adopted since the determinant $D_{pn}(1,1)$, see Eq. (8), can be obtained from the general determinant F_p , Eq. (5), by putting the quantity d everywhere equal to unity. The d 's then disappear from the determinant itself, and the quantity B becomes equal to the quantity A , see Eq. (3). Similarly the determinant $D_n(1,d)$ is obtained from the determinant $D_n(1,1)$ by replacing one of the A 's which constitute the terminal elements of the principal diagonal by the quantity B which is $A+d-1$. In the same way the determinant $D_n(d,d)$ is obtained from the elemental determinant $D_n(1,1)$ by replacing both of the A 's which constitute the terminal elements of the principal diagonal by the quantity B .

Let us now make the following definitions:*

* The author is indebted to Prof. F. D. Murnaghan for these substitutions.

$$H_p = F_p \mu^{-p} \quad (9)$$

$$\mu = + d(D_{n-1}^2(1, d) - D_n(d, d)D_{n-2}(1, 1))^{1/2} \quad (10)$$

$$\xi = \frac{D_n(d, d) - d^2 D_{n-2}(1, 1)}{\mu} \quad (11)$$

It can then be readily shown that the expansion of Eq. (5) is equivalent to

$$H_p = \xi H_{p-1} - H_{p-2}. \quad (12)$$

The condition that $F_1 = D_n(d, d)$ leads to the following definitions

$$H_0 = 1 \quad (13)$$

$$H_1 = \frac{D_n(d, d)}{\mu} \quad (14)$$

We see from an inspection of Eq. (12) and Eq. (11) that the general solution for H_p will depend upon the values assumed by the determinants which we have defined in Eqs. (6), (7) and (8). These determinants are special cases of the determinant F_p as should be evident from Eq. (5). Since a knowledge of these special cases is necessary for a complete solution, we shall digress here to consider the form assumed by F_p when we have only one group present, $p=1$.

III. SOLUTION OF CERTAIN LIMITING CASES

(A) The uniformly loaded string (Lagrange's problem).

The solution for the free periods of the uniformly loaded string, which is given by

$$D_n(1, 1) = 0$$

where

$$p = 1$$

$$d = 1 \text{ in Eq. (5)}$$

is so well known^{12,13} that we shall merely state the result here, since it will be used constantly in what follows. The determinant may be expanded yielding

$$D_n(1, 1) = A D_{n-1}(1, 1) - D_{n-2}(1, 1).$$

This gives

$$D_n(1, 1) = \frac{\sin(n+1)\theta}{\sin \theta} \quad (15)$$

if we make the substitution

$$A = (-mb\lambda)/T + 2 = 2 \cos \theta \quad (16)$$

The solution

$$D_n(1, 1) = 0$$

is given by

$$\theta = K\pi/(n+1), \quad K = 1, 2, \dots, n \quad (17)$$

The values of θ given by Eq. (17) together with Eq. (16) connecting $A(\lambda)$ and θ give us the free periods of the system. There are n possible frequencies, as is necessary for n particles.

(B) The single group of n particles with $d \neq 1$ at its terminal elements.

This case may be represented physically by a molecule, as of an organic chain compound, which is restrained at its ends by quasielastic restoring forces which differ from the restoring forces acting within the molecule itself.

Let us consider the case

$$F_1 = 0.$$

The solution in this case is exactly analogous to that of the finite wave filter,¹² and will be obtained in the same way. Let us generalize and assume that the coupling coefficient d is not the same at the two ends. The determinantal equation then becomes

$$D_n(d, d') = \begin{vmatrix} B & -1 & 0 & 0 \cdots & \cdots & 0 \\ -1 & A & -1 & 0 \cdots & \cdots & 0 \\ 0 & -1 & A & -1 \cdots & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 \cdots & \cdots & 0 & -1 & A & -1 \\ 0 & 0 \cdots & \cdots & 0 & 0 & -1 & B' \end{vmatrix} \quad n^{\text{th}} \text{ order.} \quad (18)$$

where

$$B = A + d - 1$$

$$B' = A + d' - 1$$

and all the other quantities have the same meanings as before. Direct expansion shows that

$$D_n(d, d') = D_n(1, 1) + (d + d' - 2)D_{n-1}(1, 1) + (d - 1)(d' - 1)D_{n-2}(1, 1).$$

With the aid of Eq. (15) this becomes, when $D_n(d, d') = 0$

$$D_n(d, d') = \frac{\sin(n+1)\theta + (d + d' - 2)\sin n\theta + (d - 1)(d' - 1)\sin(n-1)\theta}{\sin \theta} = 0 \quad (19)$$

It is apparent that Eq. (19) may be adjusted to any given values of the coupling coefficients d and d' . That is, we may now write the explicit expressions in terms of θ for $D_n(d, d)$, $D_n(1, d)$, $D_n(1, 0)$, and $D_n(0, 0)$ from Eq. (19). The solutions of the resulting trigonometric equations can be carried to as

high a degree of approximation as is necessary. Two cases, in which an exact solution becomes possible, are of interest.

The solution for a uniformly loaded string free at one end, $D_n(1,0)$, a case which was discussed but not carried to completion by Lagrange,⁷ is obtained by putting $d=1$ and $d'=0$ in Eq. (19). The equation for θ then readily reduces to

$$\frac{\cos(n + \frac{1}{2})\theta}{\cos n\theta \sin \theta/2} = 0$$

Whence

$$\theta = \frac{2k+1}{2n+1}\pi, \quad k = 0, 1, 2, \dots, n. \quad (20)$$

The solution corresponding to $k=0$ corresponds to a rotation and expansion of the entire system about its point of support, all the particles lying on a straight line. Besides, there are $(n-1)$ oscillatory motions.

The solution for a uniformly loaded string free at both ends, $D_n(0,0)$ is obtained by putting both d and d' equal to zero in Eq. (19). The trigonometric equation then becomes

$$\tan n\theta = 0$$

Whence

$$\theta = \frac{k}{n}\pi, \quad k = 0, 1, 2, \dots, (n-1). \quad (21)$$

The solution corresponding to $k=0$, which gives $\theta=0$ and consequently $\nu=0$, corresponds to a motion of the entire system as a rigid whole. If $k=n$, which gives $\theta=\pi$, we do not have a solution since in this case both numerator and denominator of Eq. (19) vanish and their ratio is not zero.

IV. SOLUTION OF THE GENERAL DETERMINANTAL EQUATION FOR p GROUPS, $H_p=0$

(A) Formal solution in terms of θ and Γ .

We can now proceed with the formal solution of the general determinant H_p .

$$H_p = \xi H_{p-1} - H_{p-2} \quad (12)$$

Eq. (12) is in the standard form¹² and if we make the substitution

$$\xi = 2 \cos \Gamma \quad (22)$$

the equation can be thrown into the form

$$H_p = \frac{\sin(p+1)\Gamma + d \sin(n-1)\theta/\sin \theta \times \sin p\Gamma}{\sin \Gamma} = 0. \quad (23)$$

The solution of our problem therefore consists in the solution of Eq. (23) together with our two equations of definition, Eqs. (16) and (22), which may be put in the form

$$\xi = \frac{2(1 - \cos \theta)(d - 1) \sin n\theta + 2d \sin \theta \cos n\theta}{d \sin \theta} = 2 \cos \Gamma \quad (24)$$

$$A = (-mb\lambda)/T + 2 = 2 \cos \theta \quad (16)$$

(B) Approximate solution of $H_p = 0$.

An exact solution of these equations is not, in general, possible. An approximate solution can be obtained, however, when the coupling coefficient d , is small. We have already found, Eq. (21), that when $d=0$ the values of θ are given by $(k/n)\pi$. Moreover, when $d=1$ the values of θ are given by $k\pi/(n+1)$, Eq. (17). We can therefore say, when d is small,

$$\theta_k = \frac{k\pi}{n} + \Delta\theta_k, \quad k = 0, 1, 2, \dots, (n-1) \quad (25)$$

where $\Delta\theta_k$ is a small quantity of order d or less. We shall now inquire as to the values assumed by the expression occurring in Eq. (23), $d \sin(n-1)\theta/\sin \theta$, when θ has the value given by Eq. (25). Direct substitution shows that

$$\frac{d \sin(n-1)\theta}{\sin \theta} \cong d(n-1).$$

If we will restrict ourselves to cases in which $d(n-1)$ is small in comparison with unity Eq. (23) becomes $\sin(p+1)\Gamma + (a \text{ small quantity of order } dn) \sin p\Gamma = 0$. An approximate solution for Γ will obviously lie near $(s\pi/p+1)$ and we therefore write for the solution of Γ

$$\Gamma_s = \frac{s\pi}{p+1} + \Delta\Gamma_s, \quad s = 1, 2, \dots, p \quad (26)$$

$\Delta\Gamma_s$ is a small quantity whose value is to be determined by successive approximations. In making this approximation we assume that $(p+1)\Delta\Gamma_s$ is so small that we can replace the sines of the angles by the angles themselves.

The substitution of Eqs. (25) and (26) in Eqs. (23) and (24) and the evaluation of $\Delta\Gamma_s$ and $\Delta\theta_k$ is tedious but straightforward, yielding finally for the pn desired values of θ ,

$$\left. \begin{aligned} \theta_{0s} &= 2 \left(\frac{d + d^2}{n} \right)^{1/2} \sin \frac{s\pi}{2(p+1)} \\ s &= 1, 2, \dots, p \\ (k &= 0) \\ \theta_{ks} &= \frac{k\pi}{n} + (-1)^k \frac{d}{n} \cot \frac{k\pi}{2n} \left[(-1)^k \left(1 + d - \frac{d}{2n} - \frac{d}{p+1} \right) \right. \\ &\quad \left. - \left(1 + d - \frac{d}{n} \right) \cos \frac{s\pi}{p+1} - (-1)^k \left(\frac{d}{2n} - \frac{d}{p+1} \right) \cos^2 \frac{s\pi}{p+1} \right] \\ s &= 1, 2, \dots, p \\ k &= 1, 2, \dots, (n-1). \end{aligned} \right\} \quad (27)$$

The frequencies of the free periods are obtained through the definition

$$A = (-mb\lambda)/T + 2 = 2 \cos \theta. \quad (16)$$

From this equation we readily obtain

$$\nu_{ks} = \frac{\lambda_{ks}}{2\pi} = \frac{1}{\pi} \sqrt{\frac{T}{mb}} \sin \frac{\theta_{ks}}{2}. \quad (28)$$

V. SOLUTION FOR TWO GROUPS COUPLED TOGETHER

The solution for the free periods of a system consisting of only two groups coupled together is of some interest, since the solutions can be obtained quite as directly as in the case of a single group, and can as readily be carried to any desired degree of accuracy. We shall therefore consider two cases in which there are only two groups present.

(A) Two groups coupled together and to fixed supports.

In this case in which we have two groups coupled together and to fixed supports we obtain from Eq. (5)

$$F_2 = D_n^2(d, d) - d^2 D_{n-1}^2(1, d). \quad (29)$$

The condition for a solution is, as usual,

$$F_2 = 0.$$

Using Eq. (19), ($d=d'$), and Eq. (15), this expression becomes

$$\left[\frac{\sin(n+1)\theta + 2(d-1)\sin n\theta + (d-1)^2 \sin(n-1)\theta}{\sin \theta} \right]^2 - d^2 \left[\frac{\sin n\theta + (d-1)\sin(n-1)\theta}{\sin \theta} \right]^2 = 0. \quad (30)$$

On transposing, extracting the square root, and using first the + and then the - sign, we obtain the two following equations

$$\frac{\sin(n+1)\theta + (d-2)\sin n\theta - (d-1)\sin(n-1)\theta}{\sin \theta} = 0 \quad (31)$$

$$\frac{\sin(n+1)\theta + (3d-2)\sin n\theta + (2d^2-3d+1)\sin(n-1)\theta}{\sin \theta} = 0 \quad (32)$$

The solution of these equations can be carried to as high a degree of approximation as is necessary, for any values of the coupling coefficient, d , whatever.

(B) Two groups coupled together, but with free ends.

We may also readily obtain the free periods of a system consisting of two groups of n particles each coupled together but with free ends. This means that $d=0$ at the 1st and 2 n th particles. The determinantal equation is

obtained from Eq. (5) written for only two groups when the terminal elements B of the principal diagonal are replaced by B' where

$$B' = A - 1.$$

Let us call this determinant F_2' . With the aid of these definitions we obtain by expansion as before, see Eqs. (6), (7) and (9),

$$F_2' = D_n^2(d, 0) + d^2 D_{n-1}^2(1, 0).$$

The condition for a solution is, as usual,

$$F_2' = 0.$$

With the aid of Eq. (19) this becomes

$$\frac{\sin(n+1)\theta + (d-2)\sin n\theta - (d-1)\sin(n-1)\theta}{\sin \theta} = \pm d \frac{\sin n\theta - \sin(n-1)\theta}{\sin \theta} \quad (33)$$

On expanding the multiple angles and collecting we have

$$\frac{2 \sin n\theta (\cos \theta - 1)}{\sin \theta} = 0 \quad (34)$$

and

$$\tan n\theta = \frac{d}{1-d} \cot \frac{\theta}{2}. \quad (35)$$

From Eq. (34) we have

$$\theta = \frac{k\pi}{n}, \quad k = 0, 1, 2, \dots, (n-1) \quad (36)$$

The n roots of Eq. (35) must be approximated.

It is interesting to note that if $d = \frac{1}{2}$, Eq. (35) also becomes capable of exact solution, the roots being given by

$$\theta = \frac{2k+1}{2n+1}\pi, \quad k = 0, 1, 2, \dots, (n-1)^\dagger \quad (37)$$

We obtain the free periods by means of our fundamental definition given in Eq. (16), $A(\lambda) = 2 \cos \theta$.

VI. DISCUSSION

A discussion of the results obtained here is most readily undertaken with the aid of a specific example. We have therefore represented in Fig. 2 the free periods which may be obtained from a group of 9 particles under the various arrangements discussed in this paper. For convenience the factor $(1/\pi)(T/m\bar{b})^{1/2}$ has been taken equal to unity. When we have the 9 particles

[†] Here again the value $k=n$, giving $\theta=\pi$, must be rejected due to the vanishing of the denominator in Eq. (33).

arranged in a uniform group and coupled to a supporting wall with a coupling coefficient $d=1$, we have the frequencies given by the well known formula. Eq. (17), as is shown in case (a). When the coupling coefficient between the group and the support is reduced to $d=0.1$, each of the previous frequencies is decreased, the slower ones more than the faster ones, as is illustrated in case (b). This slowing up of the frequencies with decreasing d is continued until, when $d=0$, the slowest frequency has become zero itself, see case (c). Now let the 9 particles be rearranged into 3 groups of 3 particles each, with a coupling coefficient $d=0.1$ between each group and between the end groups and the supporting walls. The 9 frequencies present rearrange themselves into three sharply defined groups of three frequencies each, see case (d). The number of groups of frequencies present is determined by the number of particles present in each group, that is by the internal structure of the

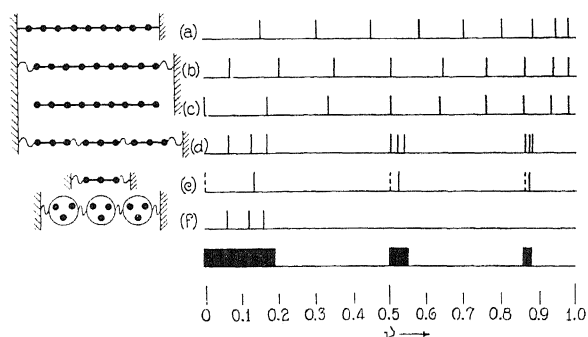

Fig. 2. The free periods obtained from various arrangements of a system consisting of 9 massive particles; $1/\pi \cdot T/m\bar{b}^{1/2}=1$

groups under consideration. On the other hand the number of separate frequencies present in each group of frequencies is determined by the total number of groups present in the system. In case (e) we have plotted the frequencies due to three particles arranged in a single group with coupling coefficient $d=0.1$. The dotted lines in case (e) represent the frequencies which would be present if $d=0$. Similarly in case (f) we have plotted the frequencies which would present if each group of case (d) vibrated as a rigid whole. We may speak of these frequencies as the "unmodified group vibrations" of such a system as that shown in case (d). Similarly the two higher frequencies of case (e) may be spoken of as the "unmodified internal vibrations." We may therefore say that the effect of rearranging a single group of pn particles into p groups of n particles each is to rearrange the pn free periods of the original group into n distinct groups of p frequencies each. Or, the effect of coupling together p originally independent groups of n particles each is to slightly modify the p slow group vibrations which would be present if each group vibrated as a rigid whole, and to split each of the $(n-1)$ internal vibrations into p separate components.

When the number of groups present has become infinite, as will be true for all practical purposes in any physical crystal, the number of frequencies

present in any one group becomes infinite and we have bands instead of groups, see case (g). The lower limit of each band is determined solely by the corresponding "unmodified" frequency of a single group with coupling coefficient $d=0$. See the dotted lines in case (e), Fig. 2. The upper limit, for any given band, is determined solely by the values of d and n , if $p=\infty$. The first and slowest band corresponds to the well-known Debye spectrum of group vibrations, but with a slightly modified upper limit.

Let us now inquire as to the distribution of the individual frequencies within these groups when p has become large but not infinite. To do this we form $(\partial\nu_{ks}/\partial s)$. From Eq. (28) we get

$$\frac{\partial\nu_{ks}}{\partial s} = \frac{1}{2\pi} \left(\frac{T}{mb} \right)^{1/2} \cos \frac{\theta_{ks}}{2} \frac{\partial\theta_{ks}}{\partial s}.$$

It is evident that the frequencies will be closest together, that is to say the density of lines in the elastic spectrum will be greatest, when $(\partial\nu_{ks}/\partial s)$ is a minimum. An investigation of the above expression with the aid of Eqs. (27) shows that, to a first approximation, the frequencies of the group, or Debye, vibrations crowd together or converge toward the high frequency limit of the group. The grouping of the frequencies is exactly analogous to that holding in cases (a), (b), and (c) of Fig. 2. In the case of the internal vibrations, to a first approximation, the frequencies converge toward both the high and low frequency limits of the group. The lines here have their minimum density at the center of the group.

It is not to be inferred from the preceding discussion of frequencies and bands that each of the frequencies predicted by Eqs. (27) can be expected to appear in the optical spectrum of the corresponding compound. The question of the optical activity of a given frequency is essentially a question concerning the electric moment of the molecule. It is hoped that an investigation of this question can be made at a later date.

VII. APPLICATION TO THE SPECIFIC HEATS OF ORGANIC COMPOUNDS

Although it is not the purpose of this paper to discuss in detail the applications of the equations just derived, an obvious example will be given. If we have, by any means, an approximate value for the forces of restitution acting upon an atom in a crystal of an organic chain compound, we have here the means for computing its free periods. By applying the proper Debye or Einstein functions we can then compute its specific heat as a function of temperature. The frequencies arising from the terms containing θ_{0s} , being molecular vibrations, will give rise to a Debye term. It is necessary then to know only the upper limit of the terms defined by θ_{0s} , that is θ_{0p} . When p becomes large this term becomes $\theta_{0p}=2(d+d^2/n)^{1/2}$. For the internal vibrations it will in general suffice to neglect the correction terms in Eqs. (27) and write $\theta_{ks}=k\pi/n$. In case the frequency band is unusually wide, as will be the case with the "internal" bands of hexyl alcohol, we may

use the average frequency of the band in the specific heat formula. Even in this case the correction is practically negligible.

For the force of restitution due to a displacement along the length of the molecular chain we will take 4×10^5 dynes/cm. This force will give a band in the neighborhood of 28μ for all our compounds. For the force of restitution due to a displacement perpendicular to the length of the chain we will take 0.12×10^5 dynes/cm. This value has been chosen more or less arbitrarily to fit the data. It is, however, of the same order of magnitude as the corresponding constants proposed by Andrews¹⁴ which range from 0.32 to 0.66×10^5 dynes/cm. It is to be noted that these constants are not forces of restitution due to a displacement along or perpendicular to the length of the valence bond itself, but are precisely as stated forces due to a displacement along or perpendicular to the length of the entire chain. The vibration of hydrogen against carbon has been neglected since others have shown that its effect is negligible.⁶

There seems to be no reliable method for computing the forces acting between the molecules in organic crystals. The Lindemann formula¹⁵ is strictly applicable to monatomic crystals, and Andrew's modification of it⁶ is of doubtful service here because of the high lack of symmetry of the chain molecules. The intermolecular forces have, therefore, been chosen arbitrarily. At low temperatures, 20°K , the internal vibrations have for the most part ceased to contribute to the specific heat. A Debye function has therefore been chosen to fit the data at this point. From the value of ν_0 so chosen it is possible to compute the corresponding force constant and the coupling coefficient d . This has been done.

The Debye function has been computed for three degrees of freedom, which assumes an isotropic crystal. The Einstein functions arising from the internal vibrations have been taken as having two degrees of freedom when the motion is perpendicular to the length of the chain, and one degree of freedom when along the length of the chain. The heat absorbed due to the expansion of the crystal has been computed according to Andrew's modification of Nernst's formula⁶

$$C_p - C_v = (C_v^2)_{\text{molecule}} \times \frac{T}{T_m} \times 0.0214$$

where $(C_v)_{\text{molecules}}$ is the specific heat at constant volume arising from the Debye terms alone, T is the temperature at which computations are being made and T_m is the melting point of the crystal under investigation.

Specific heat data are available for four of the normal alcohols. The computations have therefore been carried through for these substances. The frequencies found, neglecting the correction terms, as well as the total band width to be expected, expressed as percent of the corresponding uncorrected frequency, are summarized in Table I. In this table ν_0 represents the upper

¹⁴ J. R. Bates and D. H. Andrews, *Proc. Nat. Acad. Sci. (U.S.A.)*, **14**, No. 2, 124 (1928), D. H. Andrews, *Phys. Rev.* **34**, 1626 (1929).

¹⁵ F. A. Lindemann, *Phys. Zeits.* **11**, 609 (1910).

limit of the Debye terms, chosen arbitrarily to fit the data as stated above. The other frequencies, ν_1 , ν_2 , etc., represent the internal vibrations. The frequency bands, of width given by $\Delta\nu$, will always extend towards higher frequencies from the uncorrected frequency given in the table.

TABLE I.

	$10^{-11} \times$	ν_0	ν_1	ν_2	ν_3	ν_4	ν_5	ν_6
Methyl Alcohol	(Trans)	29	48					
	(Long)		277					
$\Delta\nu$ in %			0.6					
Ethyl Alcohol	(Trans)	25	35	60				
	(Long)		200	347				
$\Delta\nu$ in %			1.2	0.7				
Butyl Alcohol	(Trans)	48	22	41	57	67		
	(Long)		126	239	329	387		
$\Delta\nu$ in %			16	2.8	0.8	0.1		
Hexyl Alcohol	(Trans)	48	16	32	44	55	64	69
	(Long)		91	177	255	320	370	400
$\Delta\nu$ in %			36	6.4	2.3	1.0	0.4	0.1

Using these frequencies the calculations for ethyl alcohol give the following results, where $3D()$ represents a Debye function with 3 degrees of freedom, $1E()$ represents an Einstein function with 1 degree of freedom, etc.

TABLE II. *Ethyl alcohol*, $n=3$.

T°K	30	60	90	150
$3D(120/T)$	3.0	4.9	5.5	5.8
$1E(959/T)$	—	—	—	0.1
$1E(1660/T)$	—	—	—	—
$2E(166/T)$	0.5	2.2	3.0	3.6
$2E(288/T)$	—	0.8	1.8	2.9
C_v corr.	—	0.2	0.4	0.7
Total C_p , Cal/Mol	3.5	8.0	10.6	13.1

The computations for the other alcohols have been carried through and are plotted in Fig. 3, in which the solid lines represent the curves computed in the manner just indicated and the plotted points the observed values given by the authors indicated.

From the Debye functions chosen to fit the data at low temperatures we get values of ν_0 which give us values for the constant d for each substance in the manner indicated above. The results are as follows:

TABLE III.

Substance	No. groups	d
Methyl Alcohol	2	0.011
Ethyl Alcohol	3	0.012
Butyl Alcohol	5	0.070
Hexyl Alcohol	7	0.096

With the exception of ethyl alcohol the coupling coefficient varies approximately as the number of groups in the molecule. The low value of the coupling coefficient in the case of ethyl alcohol may have significance when considered in connection with the ease with which this substance forms glasses at low temperatures.

The agreement of the computed values with the observed values is as close as is to be expected, considering the very approximate nature of the calculations. There are, to be sure, no reasons for believing that these organic crystals are actually isotropic as has been assumed. Neither can we be particularly certain about the correction applied according to Nernst's formula for the conversion of C_v into C_p . The value of the constant 0.0214 was chosen originally to fit the data obtained in the case of certain metals and halogen salts,¹⁶ and we have no *a priori* reason for applying it directly

Fig. 3. C_p in cal/mol for the normal alcohols. (1) Methyl Alcohol K. K. Kelley, J. Amer. Chem. Soc. **51**, 180 (1929), (2) Ethyl Alcohol K. K. Kelley, J. Amer. Chem. Soc. **51**, 779 (1929), (3) Butyl Alcohol G. S. Parks, J. Amer. Chem. Soc. **47**, 338 (1925). (4) Hexyl Alcohol K. K. Kelley, J. Amer. Chem. Soc. **51**, 779 (1929).

to the case of organic crystals. Moreover these compounds have been treated as though each molecule was a uniformly loaded string which is actually not the case. The mass of the OH group is actually 17 as against 14 for the CH_2 group and 15 for the CH_3 group.

An additional remark should be made concerning the frequencies given in Table I. The values given under ν_0 , the upper limit of the Debye frequencies, have been chosen, as stated, to fit the data at 20°K and, so far as the comput-

¹⁶ W. Nernst and F. A. Lindemann, Zeit. f. Elektrochemie **17**, 818 (1911).

ations are concerned, may be looked upon as arbitrary constants. From these values of ν_0 values have been obtained for d which justify the original assumption that d is a small quantity. In the same way the absolute values of the frequencies of the internal vibrations are arbitrary, since the constant T/b was chosen more or less arbitrarily. These internal frequencies can therefore be considered significant only when taken in the ratio $\nu_1\nu_2\nu_3$ etc., or ν_1 (Methyl): ν_1 (Ethyl) etc. The results of applying Eqs. (27) to the computation of the specific heats of organic crystals are thus largely not characteristic of this paper. That is to say, for reasonable values of d , and within the limits of experimental error, Eqs. (27) indicate that the correction terms in the expressions for ν_{ks} are negligible, and the computation of the internal frequencies reverts to the well-known case of the uniformly loaded string with free ends.

No explanation is offered for the unusually high value of the specific heat of methyl alcohol as compared with the theoretical curve. On the other hand the manner in which the other experimental points have been reproduced by the theoretical curves is taken as evidence of the essential soundness of the underlying assumptions and calculations. If the data were available it would be highly desirable to carry through the corresponding calculations for the higher members of this or some similar series of compounds.

In conclusion the author wishes to acknowledge his indebtedness to Professor D. H. Andrews who originally suggested the problem and who has been most kind in discussing its details. The author is also indebted to Professor F. D. Murnaghan for valuable suggestions in connection with the mathematical treatment. Finally it is a pleasure to acknowledge the continual assistance of Professor K. F. Herzfeld under whose direction this paper was written.

STUDIES IN CONTACT RECTIFICATION. II. THE
CUPRIC SULFIDE-MAGNESIUM JUNCTION*BY MILTON BERGSTEIN, J. F. RINKE, AND C. M. GUTHEIL
RESEARCH LABORATORY, P. R. MALLORY AND CO., INC., INDIANAPOLIS, IND.

(Received June 19, 1930)

ABSTRACT

The commercial cupric sulfide magnesium junction consists of a disk of heat-treated, compressed cupric sulfide powder contacted under pressure with the suitably oxidized face of a magnesium disk. This rectifier is of the non-integral class and of the sulfide group. Oscillographic evidence indicates the formation of a film which possesses relatively high resistance to current flow from the magnesium to the cupric disk, slow partial destruction of the film on continued current flow in the opposite (low resistance) direction and "reformation" of the film within 0.004 sec when sufficient voltage is applied to send a current in the high resistance direction. Similar evidence indicates that there is no battery or thermoelectric effect within the junction of sufficient magnitude to account for rectification and that film "formation" and "destruction" are consequently electrothermic rather than electrolytic in origin. The phenomenon of "reverse rectification" is described. It is related to the a.c. voltage across the junction. Preliminary results for the relationship between efficiency and operating temperature of a bridge-type unit are in qualitative agreement with the theories which require film formation.

INTRODUCTION

A CONTACT rectifier is a device composed of dry dissimilar solids in good electrical contact through which current flows readily in one direction but not in the other. Contact detectors are of this class. They are merely small-current rectifiers. Rectifiers of the cupric sulfide-magnesium type and of the copper oxide-copper type are in commercial use for the rectification of large current at low voltages (usually below 120 volts). A cupric sulfide-magnesium rectifier unit of the bridge type may be made to output anywhere from 1 to 10 amperes d.c. using junctions of 0.515 sq. in. available area none of which are operated in parallel. The number of junctions used depends on the output voltage desired. The current density is higher in this type unit than in any other known commercial contact rectifier.

In a previous paper one of the authors¹ has divided rectifying junctions into general divisions according to mechanical structure and chemical constitution of the electro-negative member and has indicated what phenomena any accepted theory of contact rectification must at least qualitatively explain. Various fundamental mathematical theories² as well as

* Paper presented at the Washington meeting of the A. P. S., April 25, 1930.

symbols of a more mechanical nature³ have been used to explain contact rectification. These latter depend on an analogy between contact rectifiers and electron tubes. The first theories proposed were based on a supposed thermoelectric or battery effect at the rectifying junction. These have been subjected to some criticism.⁴ Flowers⁵ favored a theory that a blocking film was alternately formed and destroyed on each half cycle and Goddard's⁶ experiments led him to the conclusion, in anticipation of the theories of Ruben and of Slepian,³ that film formation of some kind is a necessary corollary of contact rectification.

In work on the cupric sulfide-magnesium rectifier it became necessary to establish whether film formation within the junction between the members actually did take place, under what conditions, and in what time. The results of this investigation, and other previously unstudied phenomena of this rectifier junction also, are reported herein.

According to the classification already referred to,¹ the cupric sulfide-magnesium rectifier is of the non-integral class and the sulfide group.

Fig. 1. Initiation of rectification.

EXPERIMENTAL

Nature of the rectifying junction. *Cupric sulfide disk.* The cupric sulfide disk (approximately 0.515 sq. in. in area) is prepared from compressed cupric sulfide powder which is subsequently heat treated to give a hard glassy mass and finally surface-ground to obtain a smooth finish.

⁵ A. E. Flowers, Phys. Rev. **29**, 445 (1909).

⁶ R. H. Goddard, Phys. Rev. **34**, 423 (1912).

Particular care is taken in the heat treatment process to keep well below the dissociation temperature of cupric sulfide.

Magnesium disk. Pure magnesium strip of commerce is cleaned and mildly oxidized on the surface by one of a number of suitable processes either chemical or electrolytic. The nature of the oxidizing process is immaterial to this paper provided that a complete coat not so thick as to be too highly resistant be put on. The magnesium strip is subsequently cleaned on one face and punched into disks.

The junction. The oxidized surface of the magnesium disk is then contacted with one surface of the cupric sulfide disk and the two disks locked

CuS Mg
Fig. 2. Spots of adhesion.

together in a small vise under a pressure of several thousand pounds. The force required depends on the thickness of the oxide coat. When about 4 volts a.c. is applied to such a junction it attains rectifying properties in about the first four cycles as shown in the oscillogram of Fig. 1.

The direction of free passage of current is from cupric sulfide to magnesium. If the junction should now be removed from the vise, it is found

Fig. 3. Cross section of contact spot.

that the two disks are adherent and that the junction now has rectifying properties in spite of the removal of the pressure. If the two disks are pried apart, it is found that adhesion has occurred usually over a very small area. This is illustrated in Fig. 2 in which the points of adhesion on magnesium and cupric sulfide disks from the same junction are shown. If two such disks are again contacted with each other without the application of pressure, it is found that the junction is highly resistant and does not rectify. However, if pressure and voltage be applied as before, reformation takes place usually

at some others pot. In the adhesion between the two disks actual fusion takes place. As indicated in Fig. 3 the structures of both the magnesium and the cupric sulfide are considerably changed at the contact spot. We have shown that this spot is the only place where current flow actually takes place. The simple expedient employed was to cover all of the oxidized magnesium surface except one tiny spot with a coating of insulating varnish. A very small piece of lead was placed on the magnesium behind the clear

Fig. 4. d.c. formation of junction.

spot and the whole placed in a vise and assembled with a cupric sulfide disk as indicated above. The purpose of the lead was merely to deform the disk at the desired contact point and thus to effect contact with the cupric sulfide disk, which would have otherwise been separated from the magnesium disk by the thickness of the layer of varnish. It was found that a

Fig. 5. Interruption in high resistance direction.

junction prepared in this way possessed substantially the same electrical characteristics as one prepared according to the standard practice thus establishing the fact that all the rectification and current flow takes place in the region of integral contact.

The film. Ruben³ has pointed out that the energy required for this "fusion" probably results from the I^2R loss in the oxide coating and that the

reaction results in the formation of a film to whose properties the behavior of the rectifier can be ascribed. Without examining any of the theoretical concepts involved we will here review the evidence we have accumulated indicating film formation.

Fig. 6. Interruption in high resistance direction and reversal.

If, instead of applying a.c. to the unformed junction, approximately 4 volts d.c. is applied in the direction magnesium to cupric sulfide, the junction immediately becomes highly resistant in this direction and behaves as

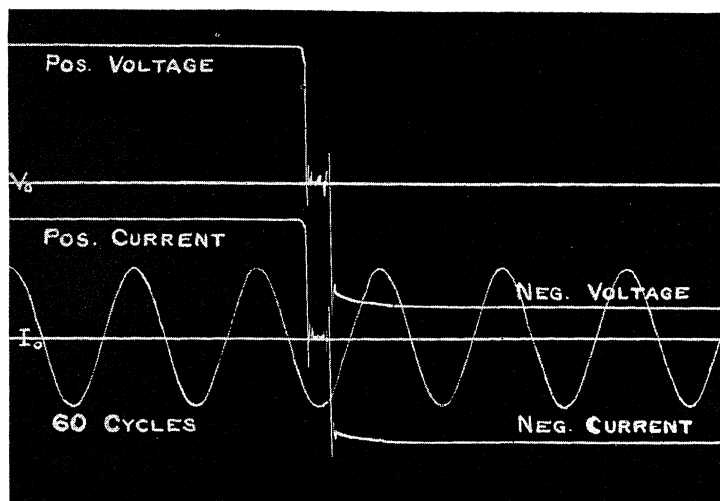

Fig. 7. Interruption in high resistance direction and reversal for cupric sulfide disk alone.

a normal rectifier when subsequently placed on a.c. The oscillogram of the development of this high resistance is shown in Fig. 4. Here we can observe that the resistance is initially extremely low but that in a period of approximately 0.02 sec. it increases to a value of the order of the final resistance in that direction.

Fig. 8. Oscillograms of interruption and reversal after various periods of current flow in the low resistance direction.

Fig. 9. Oscillograms of interruption and reversal after identical periods of current flow in low resistance direction to varying direction.

This characteristic need not be ascribed to a film. It *must* be ascribed to the building up of a resistance and a film appears to be the only source of such resistance. In Fig. 5 we show an oscillogram of current flow in the high resistance direction momentarily interrupted. In this case there is no condition of building up of resistance. The current flow returns immediately to its former value on reclosing of the circuit indicating that whatever is responsible for the high resistance persists in its existence throughout the interval.

In Fig. 6 we show an oscillogram of current flow in the high resistance direction interrupted and reversed. The current does not rise to its maximum value at once on the reversal. About 0.005 sec. is required. However, as shown in Fig. 7, exactly the same phenomenon is observed for the cupric

Fig. 10.⁷ Growth of resistance after reversal.

sulfide disk by itself between copper contacts. We would consequently be justified in saying that this oscillogram does not necessarily indicate destruction of the film lasting through that period of time. Indeed, the results obtained indicate that there is a gradual destruction of the film in a much longer time interval.

The method used in detecting this film destruction was: first, to form the junction by the regular method by applying an alternating current; second, to permit current to flow in the low resistance direction for varying periods of time; and third, to take an oscillogram at the moment of interruption and current reversal. In Fig. 8 is given a number of oscillograms taken after various periods of current flow in the low resistance direction. It is particularly notable as indicated by the increased time required to attain high resistance, that the apparent time of reformation of the film increases with the time that current has flown in the low resistance direction. Attention is pointed to the case of the unformed junction of Fig. 4 in which film for-

mation was even slower. In this case the complete interpretation of the succeeding figure in the next paragraph should be in point.

In Fig. 9 oscillograms are given for current reversals from low resistance to high resistance after identical periods of current flow but with varying voltage in the high resistance direction. The lower the voltage the longer is the time required for the high resistance to develop. This is exactly what would be expected if a definite amount of work be required to form a highly resistant intermediate layer. The oscillograms at 0.25 and 0.50 volts are, however, more difficult to explain. In these cases we do not have reformation of the film at all.

One possible interpretation of this phenomenon is that on current flow for any long time in the low resistance direction and destruction of the film small, complete, low resistance contacts are made between the cupric sulfide and the magnesium and that these contacts behave like fuses and can be "burned out" only at sufficiently high voltages. Only after "burning out" has occurred does film formation ensue. Indeed, all we may be observing in the apparent reformation of film may be "burning out" of the contacts. In Fig. 10 there is an oscillogram of a similar current reversal in which the recording film was revolved at lower speed. It can be seen that although the resistant film develops almost immediately it continues to "grow" through approximately 0.25 sec. Fig. 11 is a typical oscillogram indicating the opera-

Fig. 11. Operation of a completely formed junction as a half-wave rectifier.

tion of a completely formed junction as a half-wave rectifier. In this illustration there is no sign of any destruction or reformation of a film in the time of a half-wave, but there is evidence that a certain critical voltage must be attained before current flow starts.

Battery and thermoelectric effects. The earliest explanations presented to explain contact rectification involved the propositions that rectification resulted because of a battery or thermoelectric effect within the junction. The first evidence contrary to this theory was presented by Braun,⁴ the discoverer of contact rectification. However, this theory is repeatedly reinvented for each new case of contact rectification and it is consequently necessary to examine the evidence in point that we have collected.

In Fig. 12 is illustrated in diagrammatic form the oscillograph circuit used for this study. V and A represent the voltage and amperage galvanometer vibrators in the oscillograph respectively. J represents the junction.

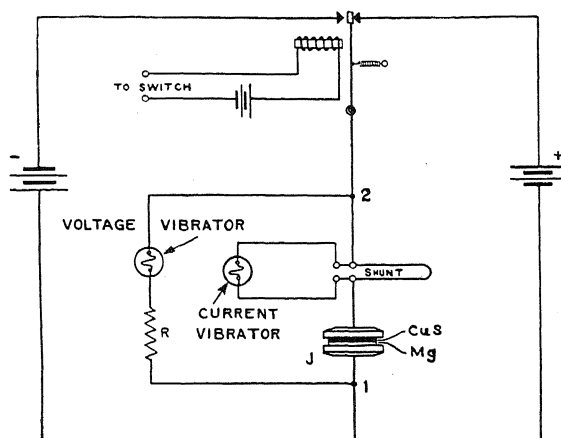

Fig. 12. Oscillograph circuit.

When current is flowing in the direction 1→2, the oscillograph can be adjusted so that the mirror displacements for V and A are in the same direction. If for any reason the circuit should be interrupted and there be a battery effect or thermoelectric effect opposed to the direction of the current, there should occur a reversal of the reading on A and a persistence of a deflection at V in the same direction as prior to the interruption. In other words, a reverse battery or thermoelectric effect will, on interruption of the

Fig. 13. Breaking circuit in high resistance direction.

circuit, give at least a momentary persistence of deflection of V . A failure to obtain this deflection, after interruption of the current in either direction, is indicated in Figs. 13 and 14. Particularly in the case of Fig. 13, where cur-

rent flow in the high resistance direction is interrupted, would this persistence of the voltage deflection be expected. The purpose of the oscillogram at *A* is merely to give an accurate indication of the time of interruption of

Fig. 14. Breaking circuit in low resistance direction.

the circuit. It is altogether possible that there may be a battery or thermoelectric effect of insufficient intensity to give an opposed deflection at *A*.

Fig. 15. Relation between d.c. amperes and impressed a.c. voltage.

The momentary opposed deflection on the current oscillograms of some figures at the moment of interruption is attributable to the inertial oscilla-

tion of the vibrator for it is similar in magnitude, direction, and period to the deflection on the voltmeter vibrator.

We may, therefore, conclude that there is no battery or thermoelectric effect in the cupric sulfide-magnesium junction of sufficient magnitude to account for its contact rectifying properties.

"Reverse rectification." The current efficiency of a rectifying junction has a theoretical maximum value for half-wave of 63.6 percent. It has been

Fig. 16. Relation between d.c. amperes and impressed d.c. voltage.

known for some time that the current efficiency is a function of the applied a.c. voltage. For example, it is evident without any intimate knowledge of the properties of a rectifying junction that above some impressed voltage it will break down and cease to rectify. At that value it is obvious that the rectification efficiency is zero. It is not so well known that for some rectifiers the rectification efficiency decreases to zero at a small a.c. voltage. Goddard,⁶ among others has pointed out that the direction of rectified current is sometimes opposed to the direction predicted by experience for the junction studied. For example, if for the cupric sulfide-magnesium junction the

rectified current would flow in the direction magnesium to cupric sulfide, we would be observing the phenomenon of "reverse rectification." Tests that we have conducted indicate that the direction of rectification is related to the impressed voltage. The results are indicated in Fig. 15 in which we have illustrated a sharp reversal of current at approximately 0.4 volts a.c. A number of tests have indicated that the reversal always takes place in this region of voltage. It would be expected from this that the resistance of the junction would be lower at low negative voltages (i.e. from Mg to CuS) than at low positive voltages. This is verified by Fig. 16 in which the direction of taking current readings is indicated by arrows. In this figure also we may be impressed by the fact that there is an apparent destruction of a film which

Fig. 17. Relation between efficiency of 4-junction bridge and temperature.

does not begin to reform until between -0.5 and -1.0 volts d.c. when reformation and negative increase of voltage are so rapid that no further readings are possible. This entire phenomenon is not made altogether clear in the light of the 0.25 and 0.50 volt oscillograms of Fig. 9 and the interpretation put on them. The conductive contacts, apparently, are of lower resistance than the film but we would expect them to carry current in both directions (if they do not "burn out") thus resulting in no rectification rather than in reverse rectification. The phenomenon will be subjected to further study.

Relationship between temperature and efficiency. The relationship between temperature and efficiency, for both power and current, is of great importance in the determination of the existence of a hypothetical film. Superficially, without too rigid analysis of the theories requiring the existence of a film in contact rectification, we may say that increase of temperature should be accompanied by lower current efficiency and, within limits, by higher power efficiency. A more detailed analysis of this aspect of the problem over a wide range of temperatures is reserved for a later paper. Fig. 17 indicates that this situation is true for a four junction bridge type rectifier.

The values graphed for power efficiency are arbitrary inasmuch as no correction has been applied for circuit conditions.

CONCLUSIONS

1. Oscillographic studies of the cupric sulfide-magnesium junction indicate film formation.
2. An explanation of the results obtained may be based on the hypothesis that "formation" of a film takes place on current flow in the high resistance direction and "destruction" on current flow in the low resistance direction for long intervals of times.
3. "Reverse rectification" is not easily explainable on any hypothesis so far presented. This problem is to be further studied.
4. The variation of efficiency of a bridge-type unit with temperature is in qualitative agreement with the requirements of theories that require film formation. This subject is to be discussed in greater detail in subsequent papers.
5. No battery or thermoelectric effect sufficient to account for the rectifying properties of the cupric sulfide-magnesium junction has been noted. It is consequently suggested that film formation and destruction are electrothermic rather than electrolytic in origin.

LETTERS TO THE EDITOR

The Presence of Neutral Oxygen in the Gaseous Nebulae

The most stable configuration, s^2p^4 , of neutral oxygen gives rise to three terms, 3P , 1D and 1S . McLennan¹ has shown that the green auroral line corresponds to the $^1D-^1S$ transition. Recently Frerichs² by a very exhaustive analysis of the oxygen spectrum has been able to predict the positions of the $^3P_2-^1D$ and $^3P_1-^1D$ transitions at $6299 \pm 5\text{\AA}$ and $6363 \pm 5\text{\AA}$ respectively while a private communication to Dr. Frerichs from Professor Paschen states that he has found these lines in the laboratory at 6300.00\AA and 6363.86\AA .

Wright's³ list of nebular lines shows weak unidentified lines at 6302\AA and 6364\AA . In agreement with the corresponding transitions in O_{III} the $^3P_2-^1D$ line is two or three times as intense as the $^3P_1-^1D$ line. The general behavior of the lines in various nebulae is in agreement with this identification.

The question at once arises as to why the $^1D-^1S$ line alone occurs under auroral conditions while the $^3P-^1D$ lines alone appear in the nebulae. The theory of the transition probability⁴ due to quadrupole radiation (as these lines are "forbidden" by the ordinary selection rules no dipole radiation exists)⁵ shows that the mean life of the 1D state before transition to the 3P level is much longer, since it is an intercombination line, than that of the 1S state before transition to the 1D state. On the other hand the number of atoms reaching the 1S state is much less than that reaching the 1D state. This follows from the fact that nearly all of the atoms reaching the 1S state make the $^1D-^1S$ transition and thus arrive at the 1D state in addition to those that reach there directly. Since the 1D state has lower energy than the 1S state the number reaching it directly is also greater than that reaching the 1S directly.

Under nebular conditions the mean time between impacts with other atoms is large compared with even the longest of these mean lives and consequently the intensity of the lines is determined largely by the number of atoms reaching the respective upper states. Consequently we should expect the $^1D-^1S$ transition to be much weaker than the $^3P-^1D$ transition. This is verified by the observation that in O_{III} and N_{II} , which have the same set of low terms, the $^1D-^1S$ line is 1/20 to 1/50 as intense as the $^3P-^1D$ lines. A corresponding ratio in O_I would give the $^1D-^1S$ line at 5577\AA an intensity much below the limit that could have been observed, as the $^3P-^1D$ lines are fairly weak.

On the other hand under auroral condition the collisions between atoms are so frequent that the atom in the 1D is almost always taken out by a collision of the second kind before it can radiate the $^3P-^1D$ lines. The $^1D-^1S$ transition, however, has a high enough probability so that even under auroral conditions it can take place before a collision of the second kind removes the atom from the 1S state.

Photoelectric Outgassing

While attempting to study the photoelectric emission from the two sides of an unbacked film of gold, 2×10^{-6} cm thick, it was found that the emission did not hold constant but increased with exposure to ultraviolet. With 360 hours of exposure of the film to ultraviolet the photo-current from the side where the light was incident increased 136 fold and at the same time the long wave limit shifted from 2000A to 2537A.

The emission from the unexposed face increased, in the first 50 hours, about one tenth as much as from the exposed face. It was found that the film was transmitting down to a wave-length of 2259A but only about 10 percent of the energy in the lines below 2537A was being transmitted. On exposure of the second face to the direct radiation of the arc its emission increased as in the case of the first face.

It was found that with the film charged positively, so that the electrons returned to the film after being ejected, the increase in emission was more rapid and the long wave limit shift was greater than when the film was charged negatively. In either case, when the film was exposed through a filter which absorbed all wave-lengths below 2800A but transmitted 55 percent of the total energy of the arc, there was no increase in emission.

A plate of solid gold was treated in like fashion and showed a similar increase in photo-current, which took place much more slowly, accompanied by a shift in long wave limit from about 2000A to 2482A.

At intervals during the exposure of the

specimen to ultraviolet fatigue curves, taken by leaving the specimen in a vacuum of 10^{-7} mm of Hg unexposed, showed during the first stages a rapid decrease in photo-current with time of standing, but, after 360 hours of exposure for the film and 160 hours for the solid gold, the photo-current from the former held constant for 3 hours, and from the latter $1\frac{1}{2}$ hours. This seemed to indicate that a fairly stable equilibrium had been reached, and the subsequent fatigue was consistent with the idea that it was due to return of gas to the surface.

The experiment was repeated, using a silver filament approximately 0.025 mm thick, and an increase in emission comparable to that for the gold film was obtained.

The probable explanation is that photoelectrons, both when ejected and returned to the surface by a reverse field, remove adsorbed gas from the surface.

Millikan¹ noted an increase in photoelectric emission on exposure of certain metals to ultraviolet, but did not note the corresponding change in long wave-length limit or that the photoelectrons themselves apparently play an important part in the outgassing.

Work is being carried forward testing this explanation and obtaining more data on photoelectric properties of thin films.

Effect of the Earth's Electric and Magnetic Fields on Ions in the Atmosphere

In a recent letter¹ Hulburt has pointed out that the westward drift of ions in the upper atmosphere predicted in a previous paper of the writer² would be prevented by collisions of ions with neutral particles which partake of the earth's rotation. The predicted westward drift was obtained by neglecting the effect of collisions; it remains to consider the modifications of the theory necessitated by taking account of the effect of collisions of ions with neutral particles which rotate with the earth. A little consideration seems to show that the steady-state solution of the problem cannot be anything else than that

contained on page 830 of the paper² already referred to, where three regions were considered, (1) the interior of the earth, (2) the lower conducting atmosphere, (3) the upper atmosphere. The argument is as follows, references being to the May 1929 paper.²

1. Consider first an atmosphere containing no ions. This is the case treated on page 827. As there are no charges in the atmosphere, the potential outside the earth must be a solution of Laplace's equation relative to non-rotating observers, and the components of electric intensity relative to observers on the surface of the earth are given by (14).

It is evident that E_r' is upward (since M is negative) for $r > a$ at all latitudes and E_θ' is directed from the equator toward the poles.

2. Now suppose a few ions to be produced or injected into the earth's atmosphere. They tend to assume a westward drift, but, as Hulburt points out, collisions with neutral molecules interfere with this drift, causing a current in the direction of the electric field. The writer has already investigated the conductivities parallel and at right angles to the field in some detail.³ This current carries negative ions downward and toward the equator, and positive ions upward and toward the poles, and if the supply of ions is sufficient charges are produced just sufficient to annul the electric field relative to an observer at rest on the surface of the earth. No matter how long the mean free paths and how few the collisions this annulment of the electric field must take place after a sufficient lapse of time.

3. Finally, then, we must have the situation expressed by the equations on page 830, the radius b , however, being that of the outermost limit of the ionized atmosphere. On the surface of the earth we have the negative charge σ_{12} increasing from 0 at the poles to a maximum at the equator. The potential throughout the ionized atmosphere is given by V_2 . The atmosphere contains the volume charge ρ_2 which is positive over the poles and negative over the equator. The total charge in a spherical shell of radii r_1 and r_2 is zero, the volume charge being due merely to a separation of positive ions which have been urged poleward from negative ions which have been urged equatorward. The volume charge ρ_2 decreases in magnitude as the altitude increases, varying inversely with r^3 . Finally at the top of the ionized atmosphere is the surface charge σ_{23} , positive over the poles and zero at the equator. Outside the ionized atmosphere the potential is given by V_3 .

4. Now consider ions produced anywhere

in the ionized atmosphere ($r < b$). They suffer no drift at all due to the electric field, and rotate with the earth in so far as this effect is concerned. The gravitational drift is all that is left.

5. The case is different with ions reaching the earth from outside. So long as they are outside the ionized atmosphere they suffer the electrical drift (16) with a replaced by b . But when they begin to suffer collisions with air molecules the ions of opposite sign are separated just as in paragraph (2). The negative ones move downward annulling the surface charge σ_{23} , whereas the positive ones move upward and poleward. Effectively, then, the surface charge σ_{23} is raised and b is made larger.

6. Now suppose that ions disappear from the uppermost region of the atmosphere during the night. Then the upper limit of region (2) is depressed, that is, b becomes less. If after sunrise new ions are produced in the upper atmosphere outside the region (2) and in the region (3) which had lost its charge during the night, these new ions start drifting westward but collisions with neutral molecules cause the positives to move polewards and the negatives equatorwards as in paragraph (5). In this way the upper limit of region (2) is raised, b becoming greater.

7. It would seem, then, that ions produced in the portion of the atmosphere which is already ionized should experience no electrical drift relative to the rotating earth. Only those ions which come into the earth's atmosphere from outside or which are produced above the ionized region should suffer the westward drift, and this they should lose in time as a result of collisions.

Note on Wave-Lengths in the Vacuum Copper Arc

Some months previous to publication, Dr. Kievin Burns sent me for criticism a typed copy of the paper "Wave-Lengths in the Spectra of the Vacuum Copper Arc" by Burns and Walters, publication of the Allegheny Observatory, Vol. VIII, No. 3. I did not fulfill my obligations as a critic

properly, for I failed to detect until recently, a rather important error which should have been obvious to me because of my previous work on the copper spark.

Burns and Walters wave-length determinations were made by the usual interferometer method which involves a preliminary wave-

length obtained from some other measurement. The preliminary wave-lengths used for Cu II lines were those given in the tables of spark spectra. Such a choice is perfectly right for low level spark lines, but unfortunately introduces an error of about 2.7 wave numbers into the results for all high level lines, since they appear with approximately that much greater wave number in arc exposures.

The authors of the paper intend to print a corrected list; but, in the meantime, it should be noted that the wave-numbers of all lines involving b^3D and b^1D of Cu II should be increased by approximately 2.7

cm^{-1} . These lines are useful as standards when they are produced in an arc, but not when the source is a spark. In the latter case they are diffuse and displaced to longer wave-length.

The great accuracy of the determination of the sharp lines of Cu II in the ultraviolet will be a boon to spectroscopists because those lines are by far the most useful as standards of measurement in the region $\lambda 2400$ – $\lambda 1940$.

The Electrolytic Dissociation of Nitric Acid as Revealed by its Infrared Absorption Spectrum

I. R. Rao has recently published an important paper in the Proceedings of the Royal Society (A127, 279, 1930) in which he describes a new method of estimating the percent dissociation of electrolytes. He has obtained relative values for the percent dissociation of nitric acid in solutions of varying concentration, which for the first time are independent of assumptions regarding the mobility of the ions. The method, which makes use of intensity studies of a Raman line scattered from water solutions of the acid and attributed to the NO_3 ion, was suggested by the earlier observations of Rao (Nature 124, 762, 1929), and independently by the observations of one of us (Phys. Rev. 35, 284, 1930), that large intensity shifts occurred in the Raman scattered lines as the acid was diluted, the presumption being that the lines which grew in intensity upon dilution arose from the NO_3 ion. Although most of this earlier work upon the Raman spectra was done by one of us in the months of April and May, 1929, publication was delayed until Rao's account of nearly identical results, in Nature, stimulated a short report in the February Physical Review. It was of course obvious that studies of the infrared absorption spectrum of the acid solutions should be made. These were begun and are still in progress. Since the work is being interrupted for a brief period, a short account of the results obtained so far seems advisable.

Records of the absorption of the acid solutions of varying concentration and of the fuming acid which contained about 5 percent water were taken on the self-recording quartz spectrograph described by one of us

elsewhere some years ago. The unexpected result obtained was that all the water solutions investigated, even the 70 percent commercial concentrated acid, in the region studied (2.4μ – 0.78μ), showed only bands which are unquestionably the water bands considerably sharpened and shifted slightly toward shorter wave-lengths, a circumstance which will be discussed in another place. It was only in the fuming acid that new strong maxima appeared which we attribute to the undissociated HNO_3 molecule. Absorption cells varying from less than 1 mm in length up to 10 cm have been employed. It is apparent that the concentration of the entity giving rise to these new maxima, which we believe to be the undissociated HNO_3 molecule, has been enormously reduced in as concentrated a solution as the 70 percent acid, reduced to a point where a column of the 70 percent acid 10 cm long showed no trace of the new maxima.

The bands in the fuming acid have been grouped into three sets, (1) a set of two due to water at 1.42μ and 0.96μ (2) a set of three which fit an anharmonic formula and extrapolate to a fundamental at 2.85μ of wave-lengths 1.47μ , 1.01μ , 0.78μ , and (3) a set of two at 2.12μ and 1.25μ which are interpreted as combinations between a fundamental observed in the Raman effect and bands of the anharmonic series. Others have appeared of whose nature it is yet too early to speak. Records of the acid vapor have been taken also as well as records of the 70 percent acid in which oxides of nitrogen have been dissolved. The vapor records exhibited, among other groups, a group forming an anharmonic

series which we believe to be the same as the series found in the liquid acid, but with every band characteristically shifted toward shorter wave-lengths. This matter is being investigated further. The records of the acid solutions of the nitrogen oxides show no trace of the fuming acid bands, a fact which indicates that these bands are not due to dissolved oxides of nitrogen. In regard to the anharmonic series found in the fuming acid, it is worth noting that the extrapolated fundamental at 2.85μ does not correspond to any fundamental yet observed by means of the

Raman effect. Rao reports a band at 3.01μ , but even this has repeatedly failed to appear on plates taken by one of us.

It is hoped that a fuller discussion can be given during the autumn months after experiments, which have been interrupted, are completed.

The Optical Excitation Function of Helium

I have just completed a study of the optical excitation function of helium under conditions which permitted, simultaneously, a study of the electrical conditions in the discharge tube and a determination of the intensities. A new variation of the photographic method has been used for the measurement of the intensities, and the discharge tube has been designed with a view to the elimination of secondary electron emission and of ionization affects. Due to this design, and to a thorough cleaning of the electrodes, the dependence of intensity on either current or pressure is linear indicating that there is no ion current. In earlier work, this linearity has been expected but not obtained.

The results for the singlet system are largely in accord with those obtained by Elenbaas¹ and Hanle.² For the triplets, double maxima as reported by Elenbaas, have been found, although the location of these maxima differs somewhat from that previously found. This disagreement is particularly pronounced in

the case of the first maxima, which Elenbaas and Hanle both found in the region between 25 and 35 volts. With the present apparatus these maxima occur at approximately 28 volts and it has been possible to correct their position and shape in accordance with the experimentally determined velocity distribution curve of the electrons and the linear relation between current and intensity. This correction shows that the maxima are actually located at the excitation potentials and are of much greater height compared with the background than the experimental curves, without correction, would indicate.

A full report on the apparatus and results will be published in the near future.

Metastable Atoms and Electrons Produced by Resonance Radiation in Neon

In studies of arcs in pure neon at a few millimeters pressure, we have observed some phenomena which indicate that the resonance radiation from the arc can travel through the un-ionized neon beyond the end of the arc for distances of 20 to 30 centimeters, or more, and the absorption of this radiation produces, by excitation of the gas and by subsequent collisions of the second kind, metastable atoms at the rate of at least 10^{13} cm⁻³ sec⁻¹. In these experiments the neon arc carrying currents of approximately one ampere was passed through a long tube between a hot cathode at one end of the tube and an anode

placed near the center. One or more collecting electrodes were placed in the tube beyond the end of the arc, and, in some experiments, movable collectors were used whose distance from the end of the arc could be varied.

The metastable atoms thus produced beyond the end of the arc diffuse into contact with the walls or with metallic electrodes and liberate electrons from the glass or metal surfaces which have velocities of the order of 5 or 10 volts. The walls thus become positively charged and within the space there is a definite concentration of electrons. If a collector is maintained at, say, 70 volts

negative with respect to the anode, the electrons emitted by it serve as a measure of the concentration of the metastable atoms. The concentration of metastable atoms diffusing out of the arc should fall to $1/e^{\text{th}}$ of its value every time the distance is increased by an amount equal to 0.4 of the radius of the tube. Within a few centimeters of the end of the arc this theoretical decrement is actually observed, but at greater distances the concentration of metastable atoms decreases far more slowly.

The width of the line corresponding to the resonance radiation in the arc is far greater than that of the absorption line in the unexcited neon, which is determined mainly by the Doppler effect. Assuming this cause of broadening of the absorption line, it can be calculated that between parallel planes the energy absorbed per unit volume in the gas is inversely proportional to the distance from the source and thus, as the end of the arc is approximately a point source of this radiation, the rate of production of metastable atoms should vary approximately inversely as the cube of the distance from the end of the arc. The observed values are in accord with this theory.

The electrons in the tube generated at the walls by the metastable atoms give to the neon a conductivity whose value can be measured, and from the known mobility of the electrons in neon gas, the concentration of electrons can be calculated. For low voltages on the collectors, the currents are determined solely by this mobility of the electrons, and the volt ampere characteristics for small currents are thus linear on both sides of the zero point. For larger negative voltages, the current becomes limited by the number of electrons that can escape from the collector. For sufficient positive voltages, the currents increase more rapidly than corresponds to the linear relationships, this being due to ions produced within the tube by the acceleration of the electrons. The experiments prove that these ions are produced by the ionization of metastable atoms rather than normal atoms, for the rate of production of ions varies approximately with the square of the light intensity. These conclusions are confirmed by experiments with a shutter placed beyond the end of the arc, which can cut off the radiation without interfering with the diffusion of

atoms, ions, etc., past the shutter. It is thus proved that the production of metastable atoms is produced by light which travels only in straight lines. The fact that when the collector is positive the electron currents are also proportional to the light intensity proves that the electrons owe their origin not to photoelectric effect from the electrodes, but to the production of metastable atoms or excited atoms. Small disk-shaped collectors have also been used in which one side, which faces the source of resonance radiation, is covered with mica so that the exposed surface cannot receive radiation, and yet the electron current was nearly as great as if the mica were placed on the back side of the collector, proving that the electron currents are generated by metastable atoms which diffuse short distances to the electrode even when the resonance radiation does not reach the electrode itself.

Since the electrons emitted by the collectors possess considerable initial velocities, and since these electrons make elastic collisions with the neon atoms, it is impossible to obtain a saturation current from these electrodes at these gas pressures, for electrons which diffuse back to the electrodes have sufficient energy to be reabsorbed by it. A theoretical investigation shows that in this case the current i_x that flows between any two electrodes is given by the equation,

$$i_x = \frac{16\pi}{3} I_0 \lambda C(V/V_0) \frac{1}{\log(1 + V/V_0)}$$

where V is the potential difference between the electrodes, V_0 is the volt equivalent of the velocity with which the electrons are emitted from the cathode, I_0 is the theoretical saturation current density of the electrons emitted from the cathode, λ is the mean free path of electrons, and C is the electrostatic capacitance between the two electrodes (expressed in centimeters). Experiments show that this equation expresses well the volt ampere characteristics of neighboring electrodes in neon exposed to resonance radiation.

On the Magnetic Deflection of Cosmic Rays

In a recent letter to this section, L. M. Mott-Smith¹ proposed an experiment for deflecting the cosmic rays in a magnetic field which made use of the magnetic induction in the inside of a magnetized iron bar.

This experiment has recently been performed by the writer, using identically the same arrangement and has been shortly described in "Rendicouti della R. Accademia Naxionale dei Lincei", Vol. XI, p. 478, March 1930.

Due to the exceedingly small frequency of coincidences, it was not possible during this first experiment to attain such an accuracy that the expected effect of electrons having a velocity of 10^9 volts lay outside of the average error. A new and more complete experimental set-up is at present under construction and will allow the application of the old method, as well as of a new method (for which Prof. Puccianti is to be thanked). The latter is based on the following principle. Above and below two oppositely magnetized iron bars, which lie close to each other in a horizontal plane, there are placed two counters with their axes parallel to the direction of magnetization. The electrons, passing through the upper counter will be either concentrated upon or deflected away from the lower counter, depending on the direction of magnetization.

Calculation has shown that, for a given size and separation of the counting-tubes, a much larger effect is to be expected from the latter method than from the former.

Moreover, for the explanation of such experiments, there are certain difficulties, which I (as well as L. M. Mott-Smith) did not consider at first. Namely, although the induction represents the average value of the microscopic magnetic field strength, it is probably not allowable *a priori* to assume that this average value is the true value which causes the electron deviation. An exact theoretical treatment of the problem has not been presented.

If the primary cosmic rays are an electron radiation, then (as has already been noted)² the earth's magnetic field must also be considered. The effect of the earth's field should be noticeable by an unsymmetric directional distribution of the intensity with respect to the perpendicular. Experiments are being prepared which will test such an effect.

Let us call V the velocity of the electrons in volts, R the earth's radius, M the magnetic moment of the earth, λ the magnetic latitude at the point of observation, θ the angle between the plane of the magnetic meridian and the direction of the path of the electrons (positive toward the east), a a constant, whose value is approximately 3×10^2 . Then the theory gives the following results. Electrons may impinge at a definite point of the earth's surface (when $V < aM/R^2$) only if the angle θ satisfies the following inequality:

$$\sin \theta > \frac{aM}{R^2 V} \cos \lambda - \left(\frac{aM}{R^2 V} \right)^{1/2} \frac{2}{\cos \lambda}$$

For example at a point where the magnetic latitude is $\lambda = 45^\circ$, if $(aM/R^2 V) = 16$ the above condition shows $\sin \theta > 0$. This means that the whole region west of the magnetic meridian is "in shadow". This case comes into consideration for electrons having a velocity of about 4.3×10^9 volt.

If $(aM/R^2 V) \cos \lambda - (aM/R^2 V)^{1/2} 2/\cos \lambda > 1$ the above inequality has no solution. This means that electrons can never impinge upon the point under consideration.

Here, however, diffusion and loss of velocity in the earth's atmosphere have not been taken into account.

BOOK REVIEWS

Structure of Line Spectra. PAULING AND GOUDSMIT. Pp. 263, figs. 68. McGraw-Hill Book Company, New York, 1930. Price \$3.50.

Goudsmit has often expressed the well-founded opinion that the phenomenally rapid rise of the Bohr theory was due more to the enthusiastic optimism of Sommerfeld than to the brilliancy of Bohr. The exposition of the Bohr-Hund theory that Pauling and he have given recently in their book, "Structure of Line Spectra," shows very markedly their conviction that optimism is also the proper treatment for a theory even when it is as fully developed as the Hund theory now is. I think most physicists will disagree with that idea. A severely critical attitude toward an established theory is much more apt to stimulate the increasingly difficult investigations which are necessary as the theory advances. The book under review will not accomplish that purpose for it leaves one with the impression that here is a practically closed chapter of physics. It seems regrettable that the authors have adopted such an attitude.

It is well known that the wave mechanics gives all the ordinary rules of spectra correctly, but it is also well known that most physicists would find it impossible to grasp the theory of spectra if it were presented solely as a problem in wave mechanics. The authors have wisely chosen to base their discussion on a vector model which can be easily visualized and which represents reasonably well the phenomena which can only be exactly described in terms of the quantum mechanics. Wherever necessary, the more correct methods and results of the mechanics are introduced, and references are made to the discussions of the same problems in Condon and Morse's "Quantum Mechanics."

The material is excellently arranged and is very lucidly explained. Goudsmit has always used the simplest methods to great advantage in his original papers, and the experimental spectroscopist will be grateful that that simplicity rules in this book. Particularly well-done is the discussion of hyperfine structure, which has recently assumed such importance. Goudsmit has been the leader in that part of the subject, and we can confidently expect him eventually to clear up the rather grave difficulties which, as he points out, still remain.

But, excellent as is this book, I cannot help regretting that the authors have not seen fit to make it a much more complete description of the theory and material of the subject. In many ways it falls behind Hund's "Linienpektren" published in 1927, particularly in the discussion of the relations between complicated spectra. Russell's papers on the energy of removal of electrons from various types of structure are very important for the understanding of spectra, but no discussion of such matters, nor of the limits of series in complicated cases, is given. The latter point should have been considered, if only because Hund's book contains erroneous conclusions.

It is worth drawing attention to the following statements which I believe are inaccurate or misleading. On page 71, Preston's rule for the Zeeman effect of series is stated without any qualification. That rule is true for the special case dealt with but is not generally true. On page 91, it is stated that all the symbols down to Z are needed to account for *observed* spectra. That is yet to be proved. On page 94, it is stated that triplet singlet combinations will "usually" appear not at all or with small intensities. The accuracy of that statement depends upon one's definition of "usually." Considering the authors of this book, the statement on page 98 is strange, "Thus $^3S-^3P$ consists of two lines $^3S_1-^3P_0$ and $^3S_1-^3P_2$." It is noted on page 139 that the intensity ratio for the combination $^2S-^2P$ is well verified by experiment on the sodium D -lines, but no mention is made that experiments on other similar pairs of lines disagree radically with the theory. On page 166 there are given rules governing the positions of terms within a configuration. Those rules are in reality fulfilled rather seldom except for the lightest atoms. One of the outstanding difficulties of interpretation is in direct violation i.e. the existence of inverted doublets in alkali spectra. This is not mentioned.

It is unfortunate that the authors did not choose to follow the recently accepted notation in which capital letters are used for the resultant quantum vectors of the atom.

Pauling and Goudsmit have written in this book an excellent account of the explanation of line spectra; but their optimistic attitude has prevented them from making it the complete account that many of us were expecting and that they are quite capable of giving.

A. G. SHENSTONE

The Analytical Expression of the Results of the Theory of Space Groups. RALPH W. G. WYCKOFF. 2nd edit. Pp. 239, figs. 222. Paper covers. Carnegie Institution of Washington 1930.

The first edition has long been out of print and in much demand, so that a simple reprinting would have met a very real need. The second edition, however, does far more than meet this need. The text has been completely rewritten in a more logical manner and, in most instances, with greater lucidity. The only additions here which are of doubtful value are the too greatly abbreviated discussions of the new space-group symbols of Hermann. Mere insertion of these symbols, and reference to the extensive original papers, would have been adequate. An important addition to the tables (132 pp.) of equivalent point coordinates and sub-groups for the 230 space-groups is the series of 200 well-planned and carefully drawn diagrams showing the *special* point-positions for all distinguishable cases. Drawings which show the distribution of symmetry-elements and *general* point-positions are available elsewhere, but these new diagrams with the information on sub-group symmetry contained in their captions, should be of great service in the solution of crystal structures by x-ray methods. The text diagrams are not quite as well drawn as those just mentioned. The original edition was remarkably free from errors. All the serious misprints known to the reviewer have been corrected in the new edition and in the parts newly set (the principal tables were copied photographically) only three trivial mistakes, easily corrected by the casual reader, have been noted in a rather careful survey. The author has always been a stickler for accuracy and has here upheld his principles to the letter.

L. W. MCKEEHAN

Das Ultrarote Spektrum. CL. SCHAEFER AND F. MATOSSÌ. Struktur der Materie X, Pp. 400, figs. 161, Julius Springer, Berlin, 1930. Price bound, R M 29.80.

Those interested in infrared spectroscopy have been very much pleased that during the past year and a half three excellent books have appeared on the subject. While each of the three has had its particular virtues, the volume by Schaefer and Matossi, the tenth of the Struktur der Materie monographs, is perhaps the most comprehensive and will be found to be the most generally useful.

The authors have devoted their first chapter to a careful description of the methods and instruments used in the measurement of infrared spectra. The second chapter deals with the source of infrared radiation, the hot body, and here the laws of black body radiation are given, as well as the measurements of actual hot bodies. The next chapter contains an account of the application of Maxwell theory and the manner in which the electrical and spectroscopic constants of a substance are related. The theory of the grating is also discussed.

The fourth chapter, of over a hundred and twenty pages, deals with the infrared spectra of gases and fluids. Following an exposition of the experimental methods, the authors develop the theory of the diatomic rotator-vibrator both by means of the classical and the wave theory and these results are carefully compared with the experimental data on HCl and other gases. The latter part of the chapter is devoted to a collection of the infrared data on polyatomic molecules together with many of the theories that have been proposed for their explanation. The fifth and last chapter deals with the infrared spectra of solid bodies. Beginning with the Born crystal lattice theory a fine account is given of all the more important experimental and theoretical material which forms the basis for our knowledge of this interesting subject.

It appears that this volume by Schaefer and Matossi may well be one of the important source books for the infrared for some years to come. It is an excellent compilation of all the available experimental material together with a sufficient account of the underlying theory to make the observational results intelligible. The treatment is very clear and the emphasis

which is placed on the theoretical interpretations tends to dispose of the difficulty that a survey of this character must always be somewhat uncritical in nature. The book may be enthusiastically recommended to those who are interested in the subject of the infrared.

D. M. DENNISON

Handbuch der Experimentalphysik. Herausgegeben von W. Wien und F. Harms unter Mitwirkung von H. Lenz. Band 24, 2. Teil. Röntgenspektroskopie. AXEL LINDH. Pp. viii + 436, figs. 197. Akademische Verlagsgesellschaft. Leipzig 1930. Price bound. R M 42.

When Siegbahn wrote his textbook on the spectroscopy of x-rays, he treated mainly the standard experimental methods and the general regularities in the spectra. The value of Lindh's book, aside from its bringing the bibliography up to 1929, lies chiefly in its shift of emphasis from these general regularities to the exceptions, such as the satellites of x-ray lines and the influence of chemical binding upon an atom's spectrum. The author's contributions in this last field prove him well fitted to discuss it.

After a general discussion of apparatus and gratings, the author considers the different series in detail and gives a general table of levels, revised to 1926. There is a short elementary chapter on the interpretation of the discrete x-ray spectrum. Intensity measurements, the continuous spectrum, and the auxiliary topics of the magnetic spectra of photoelectrons and photoelectric critical potentials, have their own chapters. The Compton effect is not mentioned.

A great part of the volume is given over to the compilation of data, which, when done critically or in connection with still mooted issues, is of course valuable in a handbook of experimental physics. But the inclusive reproduction of tables and figures from old work which can be seen now in some perspective, can hardly be justified. The devotion of a dozen pages to the square roots of all line frequencies (in addition to like data for absorption edges *and* term values), and the reprinting of four figures (122-125) of different ages giving $(\nu/R)^{1/2}$ as a function of Z , instead of one from the author's compiled table, are examples of such practise.

The interpretation of the lines would have been clearer if the author had given the modern spectroscopic L and J values of the levels, and shown in unified tables the two terms associated with each line, as well as the esoteric Greek notation.

J. MACK

Grundlagen der Hydromechanik. L. LICHTENSTEIN. Pp. 506, figs. 54. Julius Springer, Berlin, 1929. Price bound, R M 39.60.

This book by the well-known mathematician of the University of Leipzig constitutes volume 30 of the Springer collection *Die Grundlehren der mathematischen Wissenschaften in Einzeldarstellungen*. As might be expected it is very different from every other treatise on hydrodynamics, for the author, the fundamental problem of hydrodynamics is the integration of certain systems of partial differential equations with assigned boundary conditions and he calls to his aid all the resources of modern mathematics. This makes necessary a large amount of preliminary material; the first chapter is devoted to topology, the second gives a brief but interesting account of vector-analysis, the third treats potential theory, a subject to which the author has made valuable contributions, and so on. It is not until we reach page 290 that the equations of motion are derived. One of the most interesting and important chapters of the book is that devoted to the propagation of discontinuities, a difficult subject, the understanding of which is essential to any comprehension of wave motion. The last chapter is devoted to existence-theory questions.

The book could not profitably be recommended to a beginner, but to one who has studied Lamb and who wishes to understand more fully the mathematical foundations of the subject it should prove very valuable. For practical applications of the theory one must still turn to Lamb and to some such book as Tietjen's account of Prandtl's lectures on hydro- and aeromechanics. The printing has the high degree of excellence we have come to expect in the books of the Springer collection.

FRANCIS D. MURNAGHAN

Einführung in die Theoretische Physik. A. HAAS. Vol. I, Pp. X + 396 with 67 figures. Fifth and Sixth Editions. W. de Gruyter and Co., Berlin and Leipzig, 1930. Price bound R M 16.50.

In these last editions the subject matter of Professor Haas' excellent Introduction to Theoretical Physics has been completely worked over, and extensive revisions made both in arrangement and content. Whereas the third and fourth editions of the first volume, from which the English translation was prepared by Verschoyle, contained only two parts—Mechanics, and Theory of the Electromagnetic Field and of Light—, a third part on Thermodynamics has been added to the present editions with a consequent increase in length of some 90 pages.

The subject is developed in the author's customary clear and forceful style and the logical arrangement emphasizes the unity of the subject. Vector methods are used freely throughout the book, the theorems of vector analysis being developed as required. In spite of the fact that some writers in German are beginning to use at least parts of Gibbs' significant notation, the author adheres to the clumsy parentheses and brackets, grad's, div's and rot's. A comparison of any vector equation of a little complexity in the parenthesis-bracket notation (such as that on top of page 38) with the same equation in Gibbs' notation, would seem to be all that is necessary to convince anyone of the superiority of the latter.

Pedagogically the text may be criticized in that too frequently abstract theory is developed without any immediate application. Thus the deduction of Hamilton's canonical equation would appear more important to the student encountering them for the first time if the author had proceeded to the Hamilton-Jacobi equation and applied it to the solution of a few problems. Again Euler's equations for the rotation of a rigid body are developed without any considerable application being made.

As usual with Professor Haas' works, a high degree of scientific accuracy is maintained and misprints are nearly non-existent. These last editions will undoubtedly enjoy the high popularity of the earlier editions. The printing is excellent, but in this age of machinery it ought to be unnecessary for the reader to cut every page from preface to index.

LEIGH PAGE

Theoretische Physik. GUSTAV JÄGER. In five volumes. Vol. I Mechanik, Pp. 150; Vol. II Schall und Wärme, Pp. 133; Vol. III Elektrizität und Magnetismus, Pp. 151; Vol. IV Optik, Pp. 148, Vol. V Wärmestrahlung, Elektronik und Atomphysik, Pp. 130. W. de Gruyter and Co., Berlin and Leipzig, 1930.

These tiny volumes ($4\frac{1}{4}'' \times 6\frac{1}{4}''$) can be slipped in the pocket of the student who wishes to prepare for examination during his vacation. While elementary calculus is used freely, the mathematics is of the simplest. The first volume takes up the mechanics of particles including damped simple harmonic motion and Keplerian motion, mechanics of rigid bodies going as far as the symmetrical top under gravity, Lagrange's equations, the special relativity theory, the elements of the theory of elasticity, hydrodynamics of perfect fluids, Poiseuille's formula. The first quarter of Vol. II is devoted to the elements of acoustics, the remainder being concerned with conduction of heat, thermodynamics and kinetic theory of gases. Vol. III deals with electrostatics, magnetostatics, current electricity, electromagnetic induction, alternating currents, going as far as the development of Maxwell's equations. The volume on optics takes up the usual topics of geometrical and physical optics, and some electromagnetic theory of light, ending with a short section on x-rays. The last volume contains the theory of heat radiation, including the Stefan-Boltzmann law, Wien's displacement law and Planck's law, quantum theory of specific heats, the motion of electrons in electric and magnetic fields, metallic conduction, conduction in gases, deflection of alpha-rays, Bohr theory of the hydrogen atom, photo-electric effect, and Compton effect.

The books are clearly printed in type of normal size and strongly bound. The material is well chosen and the subject matter developed clearly and logically although in somewhat concise form. Each volume is provided with table of contents, index, and references for collateral reading.

THE PHYSICAL REVIEW

REPORT ON NOTATION FOR SPECTRA OF DIATOMIC MOLECULES

BY ROBERT S. MULLIKEN

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received March 18, 1930)

I. INTRODUCTION

FOR some time there has been much confusion and little agreement between different investigators in the field of band spectra, in respect to the symbols used for quantum numbers, spectroscopic terms, spectrum lines, and molecular constants as obtained from spectrum analysis. In the hope of remedying this situation, a number of those interested in the subject discussed the matter at Washington in April, 1929, and reached a tentative agreement on certain main points. The writer then undertook to obtain further discussion by correspondence, and for this purpose sent out on August 10 a circular letter embodying the results of the above discussion, somewhat modified and amplified as a result of subsequent experience. Copies of this letter were sent to about eighty spectroscopists. Many replies were received, and the matter was also discussed at the Faraday Society symposium on band spectra at Bristol in September.¹ On the basis of the foregoing, and of the replies to a second circular letter, sent out November 1, and of considerable additional correspondence with various individuals, the following report was prepared in tentative form, and copies were sent out with a third circular letter on March 15, 1930. After some changes based on replies to this third letter, the report is now presented.

In this report, the expression "it is recommended" is used in some cases, "it is suggested" in others. The *recommendations* represent the opinion, either active or acquiescent, of nearly everyone whose opinion has become known to the writer. They deal for the most part with important points about which definite conclusions have been reached. The *suggestions* are of a more tentative character. They deal in part with less important points and with matters where the need of general agreement is less imperative than in the case of the

¹ "Molecular Spectra and Molecular Structure. A General Discussion held by the Faraday Society." Published in book form (Gurney and Jackson, 1930), also in Trans. Faraday Soc., pp. 611-950 (1929). In regard to nomenclature, cf. pp. 628-633 and pp. 768-772 and the Errata.

recommendations. In part they refer to topics which have not yet been sufficiently discussed to make definite recommendations.—In all the proposals given, the attempt has been made to take properly into account the varied needs of experimentalists and theorists.

The recommendations and suggestions given here have been made in such a way as to supplement and to be in harmony with those in the recent Report on Notation for Atomic Spectra.² In particular, the principle of using capital letters for quantum numbers representing angular momenta belonging to the molecule as a whole, and small letters for angular momenta of individual electrons, has been adopted. The recommendations apply for the most part only to diatomic molecules, but the manner of their extension to polyatomic molecules is in some cases obvious. Although a standard notation for polyatomic molecules would be very desirable, our knowledge of their spectra is as yet so undeveloped that it is perhaps best not to attempt this now. The only recommendation made here is that any notation chosen for polyatomic molecules be such as to harmonize with and supplement those used for atoms and diatomic molecules.

In addition to making recommendations and suggestions, opportunity has been taken to discuss a few matters of definition and nomenclature in regard to which misunderstandings have arisen or are likely to arise (Λ -type doubling, p -type multiplicity, band-origins, system-origins, "electronic," "vibrational," and "rotational" energy, etc.).

II. QUANTUM NUMBERS FOR MOLECULE AS A WHOLE

General. For the *vibrational quantum number*, v is recommended to replace the hitherto usual symbol n .³ The quantum number v has integral values (0, 1, 2, \dots), the vibrational energy being given by $E_v = (v + \frac{1}{2})h\nu_e + \dots$ (in regard to ω_e , cf. Section V).

For the resultant angular momentum of any molecule, and its projection on an external field, the quantum number *designations* J and M are respectively recommended ($M = J, J-1, \dots, -J$). These designations are identical with corresponding designations for atoms.⁴ The possible J values are 0, 1, 2, \dots for molecules with an even number of electrons, $\frac{1}{2}, 1\frac{1}{2}, \dots$ for those with an odd number. In certain coupling cases, J loses its meaning, and another quantum number K becomes prominent; in singlet states, J and K are identical, and may be used interchangeably: cf. p. 615 below.

Normal coupling: *Hund's cases a and b.* Before speaking in more detail about various quantum numbers associated with the angular momenta of

² H. N. Russell, A. G. Shenstone, and L. A. Turner, *Phys. Rev.* **33**, 900 (1929).

³ This change has been urged by a number of people, because of the increasing need of referring to v in the same paper, or even in the same sentence, in which n is used to designate the principal quantum number of an electron. The symbol v has already been used by J. H. Van Vleck (*Phys. Rev.* **33**, 477, 1929) and subsequently also by others.

⁴ The use of J both for resultant *atomic* and for resultant *molecular* angular momentum is likely to cause some confusion. If its use were less well established for molecules (in the form j), J ought perhaps to be replaced by some other symbol, such as P (Hund proposed the symbol p). If this were done, M for molecules should also be replaced by another symbol.

electrons and nuclei in various coupling cases, it is desirable to review briefly the underlying theory.⁵ We have always as angular momentum elements (1) the orbital angular momentum of the electrons, (2) their spin angular momentum, and (3) the angular momentum of the nuclear rotation. There are two coupling cases which may be regarded as normal,—cases *a* and *b* of Hund.

In both cases *a* and *b* we have for the resultant angular momentum of *spin* of the electrons a quantum number *S*, exactly as in an atom. Further, we have a quantum number [formerly called i_l , or σ_k or σ_l] for which the designation Λ is here recommended; $\Lambda h/2\pi$ represents (the numerical value of) the projection, on the electric axis of the molecule,⁶ of the resultant orbital angular momentum of the electron system. The resultant orbital momentum itself is not at all rigorously quantized in molecules; nevertheless in comparing a molecule with the atom which would be obtained if its nuclei could be united, a resultant orbital quantum number *L* may sometimes be assigned as in the case of the atom; then Λ is the projection of *L*.⁷ The possible values of Λ are 0, 1, 2,

In case *a* (possible only if $\Lambda > 0$) we have strong coupling of *S* to the electric axis, as a result of the magnetic field associated with Λ . Here the projection of *S* on the axis is a quantum number [formerly called i_s , or σ_s] for which the designation Σ is now recommended.^{7,8} Σ has values *S*, *S* − 1, . . . − *S*; it is considered to be a positive or negative quantity according as it is parallel or antiparallel to Λ . The numerical value of the algebraic sum of Λ and Σ is a quantum number [formerly called *i*, or σ] for which the symbol Ω is recommended. For given values of Λ and *S*, Ω has values $\Lambda + S$, $\Lambda + S - 1$, . . . $|\Lambda - S|$.⁹ $\Omega h/2\pi$ is the total angular momentum parallel to the electric axis. This may be considered as combining vectorially with the angular momentum of the nuclei (a vector perpendicular to the electric axis)¹⁰ to give the resultant angular momentum of the molecule (quantum number *J*, cf. Fig. 1). The possible values of *J* are Ω , $\Omega + 1$, $\Omega + 2$, The quantum num-

⁵ F. Hund, *Zeits. f. Physik*, **36**, 657 (1926). For further details, cf. R. S. Mulliken, *Reviews of Modern Physics* **2**, 60 (1930).

⁶ *I. e.*, on the line joining the nuclei.

⁷ More accurately, according to the new quantum mechanics, the resultant orbital angular momentum is $L^* h/2\pi$, where $L^* = [L(L+1)]^{1/2}$; then Λ is the projection of L^* (each in units $h/2\pi$). Similarly the angular momenta associated with *S*, *K*, *J*, J^a , *R*, *l*, are, in units $h/2\pi$, really S^* , K^* , etc., and Σ is really the projection of S^* , etc. [A recommendation of the symbols L^* , S^* , etc. is not intended here.]

⁸ Σ (Greek *S*) has been chosen,—after much discussion (the use of Greek *X* was at first proposed),—for the projection of *S*, in spite of the other common uses of this symbol, because its use here is analogous to that of Λ (Greek *L*) for the projection of *L*, and to the use of the symbols Σ , Π , Δ , . . . , (Greek *S*, *P*, *D*, . . . ,) for states with $\Lambda = 0, 1, 2, \dots$, as compared with *S*, *P*, *D*, for $L = 0, 1, 2, \dots$.

⁹ Usually, for a given Λ , a given value of Ω occurs only once, but if $S > \Lambda$, one or more values of Ω occur twice. For example, if we have $\Lambda = 1$, $S = 1\frac{1}{2}$, we have $\Omega = 2\frac{1}{2}, 1\frac{1}{2}, \frac{1}{2}, -\frac{1}{2}$ corresponding to $\Sigma = 1\frac{1}{2}, \frac{1}{2}, -\frac{1}{2}, -1\frac{1}{2}$.

¹⁰ The component of angular momentum perpendicular to the electric axis, which in the text is for brevity called "the nuclear angular momentum," is really *mainly* angular momentum of the nuclei, but *also* includes small contributions from orbital (and spin, in cases *a* and *c*) angular momenta of the electrons. Cf. R. S. Mulliken, reference 5.

bers associated with the molecule as a whole in case *a* are thus v ; L (sometimes, but never very rigorously quantized), Λ ; S , Σ ; Ω , J , M .

In case *b* we have Λ and S just as in case *a*, but S is not coupled to the electric axis, and there is no quantum number Σ . Case *b* exists whenever the magnetic field associated with Λ is too weak to couple S to the axis, a condition which is possible for any value of Λ , but which is automatically fulfilled when $\Lambda=0$. In case *b*, $\Lambda h/2\pi$ and the nuclear angular momentum¹⁰ combine to give a quantized resultant (cf. Fig. 1). For the corresponding

Fig. 1. Angular momentum vectors in Hund's cases *a*, *b*, *c*, *d*, expressed in units $h/2\pi$. In cases *a*, *b*, *c*, the angular momentum of the nuclear rotation¹⁰ is represented by N , which is *not* a quantum number; in case *d* it is represented by the quantum number R . In all the figures, the horizontal base line perpendicular to N represents the direction of the electric axis (line joining the two nuclei). In cases *a* and *b*, Λ is shown as the projection of L , which is represented as precessing around the direction of Λ , i.e. around the electric axis; L is given by a dotted line to indicate that it is not rigorously quantized. In case *a*, Σ is shown as the projection of S , which is represented as precessing around the electric axis.^{12a} In all cases, each pair of vectors which form a *resultant* must be thought of as precessing around the latter with a frequency which differs for each such pair. In each case, the only vector whose direction remains fixed is J . Precessing pairs are: Λ and N around J in the case $S=0$; Ω and N around J in cases *a* and *c*; Λ and N about K , and K and S about J , in case *b*; L and S about J^a in case *c*^{12a}; R and L about K , K and S about J , in case *d*. [The use of N in Fig. 1 is not intended as a notation suggestion to be followed. In Ref. 5 the writer has used O where N appears here, and has used N with a somewhat different meaning than here.]

quantum number [formerly called p_l or j_k] the designation K is now recommended.⁷ The possible values of K are Λ , $\Lambda+1$, $\Lambda+2$, \dots . There is usually a small magnetic field in the molecule parallel to K , so that K and S form a resultant J (cf. Fig. 1).^{7, 11} The quantity $J-K$ is often called ρ ; ρ is approxi-

¹¹ The combination of K and S to give J in a molecule is closely analogous to that of L and S to give J in an atom, and the designation K has been chosen with this in mind.

mately equal to the component of S parallel to J or K ; ρ has sometimes been thought of as a quantum number, but this is incorrect. The splitting of a rotational level with given K into two or more levels differing in J might be referred to as ρ -type multiplicity (the expression " ρ -type doubling" has been in common use for the case $S=\frac{1}{2}$). This is, however, not recommended. Such an expression as "case b spin multiplicity" would be better.

In the presence of a "weak" external field J gives M . If the field is strong enough, however, the coupling of K and S is broken down (molecular Paschen-Back effect) so that J loses its significance, while K and S separately give projections for which the designations M_K and M_S (magnetic quantum numbers) are recommended. (M_K has as possible values, $K, K-1, \dots, -K$; M_S has values $S, S-1, \dots, -S$). Here $M = M_K + M_S$.

Sometimes the coupling of K and S in case b is practically zero; this situation can conveniently be distinguished as case b' . In case b' , J is without significance. When $S=0$, cases a and b' become identical, as do K and J (cf. Fig. 1); here either K or J may be used to designate the resultant angular momentum; the designation K is the better in comparisons with case b' or b states with $S>0$, the designation J in comparisons with case a states.

Other coupling cases. In addition to cases a and b there are other less common cases which are nevertheless of sufficient importance to deserve consideration here. Hund's "case c " is an ideal limiting case in which L is assumed to be as rigorously quantized as in an atom, and, also, to be so strongly coupled to S as to give a quantized resultant as in an atom. *It is recommended that this resultant, which in an atom would be called J , be called J^a in the case of a molecule.*^{12, 12a} Λ and Σ here have no (quantum) meaning, but Ω is rigorously quantized, and is (the numerical value of) the projection of J^a on the electric axis. Ω has as possible values, J^a, J^a-1, \dots down to 0 or $\frac{1}{2}$ according as J^a is an integer or a half integer. Ω combines vectorially with the nuclear angular momentum to give J as in case a (cf. Fig. 1). In an external field J gives M .

In Hund's "case d ," examples of which are found in the higher electron levels of H_2 and He_2 , L is as rigorously quantized as in an atom,¹³ but is unusually little influenced by the electric axis, so that it does not give a projection Λ on the axis. S also exists as usual, but it does not give a projection Σ . In case d the angular momentum of the nuclei by themselves is quantized; for this the quantum number R [same as Hund's p_r] is recommended. ($R=0, 1, 2, \dots$). L is weakly coupled to R to give a resultant for which the designa-

¹² The superscript a serves to indicate the relation to the atomic J .

^{12a} There is also another, probably more important, form of case c in which L , J^a , and even S are not at all rigorously quantized, and in which Ω is the only rigorous electronic quantum number of the molecule. This case is found in loosely-bound molecular states formed by the union of two atoms one or both of which when alone has its own L and S strongly coupled to each other.

¹³ Actually in He_2 the relations are more complicated: we have essentially case b for the inner electron or electrons, but case d for the excited electron, whose l is coupled in accordance with case d to an R which is really the K of the He_2^+ ion.

tion K is recommended; K has the values $R+L$, $R+L-1$, \dots , $|R-L|$.¹⁴ K and S may now combine vectorially to give J , exactly as in case b (cf. Fig. 1.). In external fields we have, (1) in "weak" fields, a quantum number M as in previous cases; (2) in "strong" fields, M_K and M_S as in case b ; (3) in stronger fields, M_R , M_L , M_S . If, as is true in H_2 and He_2 , the coupling of K and S is very small, J is lacking in significance, just as in case b' . When $S=0$, we have $K \equiv J$. In such cases, we may speak of case d' . The quantity $K-R$ in case d' , like $J-K$ in case b (cf. above) is frequently called ρ ; ρ is here approximately equal to the component of L parallel to K or R ; it is not a quantum number.

As a variation on case d , we might have "case e ," in which L and S are coupled to give a J^a as in case c , while J^a and R give a resultant J .

III. TERM SYMBOLS

For coupling cases approximating Hund's a or b , or intermediate between them, the use of the symbols Σ , Π , Δ , Φ , Γ , H , \dots to indicate $\Lambda=0, 1, 2, 3, 4, 5, \dots$ is recommended. [Until recently the symbols S, P, D, \dots have been used for $\Lambda=0, 1, 2, \dots$ as well as for $L=0, 1, 2, \dots$.] In coupling cases resembling or tending toward case d , or also in theoretical discussions where a molecule is to be compared with the atom obtainable by uniting its nuclei, L values can be indicated by using the symbols S, P, D, \dots for $L=0, 1, 2, \dots$. To indicate both L and Λ , symbols such as $P\Sigma$, $D\Pi$, etc., may be used.

The multiplicity (equal to $2S+1$) should be indicated, as in the case of atoms, by a superscript at the left, as $^1\Sigma$, $^2\Pi$, etc. In coupling cases approximating case a , it is recommended that the value of $\Lambda+\Sigma$ be indicated by a subscript at the right.¹⁵ (For singlet states, however, no subscript is needed, since $\Sigma=0$ always, so that $\Lambda+\Sigma=\Lambda$; while for case b states no subscript is possible, since a quantum number Σ does not exist). Examples, $^1\Sigma$, $^1\Pi$, $^2\Sigma$, $^3\Delta_2$, $^4\Pi_{2\frac{1}{2}}$, $^4\Pi_{1\frac{1}{2}}$, $^4\Pi_3$, $^4\Pi_{-3}$.¹⁶

There are two kinds of Σ states, which differ in respect to the symmetry of their wave-functions with respect to a plane through the line joining the nuclei. In the one kind the *electronic factor* of the wave-function ψ (corresponding to the motion of the electrons with reference to the nuclei) is unchanged on reflection in such a plane, in the other kind it changes sign.

¹⁴ K in case d has a somewhat different physical meaning than K in case b , but is exactly like the latter in that it combines with S to give J . Further, there is a one to one correspondence between the K values in case d and those in case b , and K is quantized throughout the whole range of intermediate cases.

¹⁵ The recommendation that the value of $\Lambda+\Sigma$, rather than that of Ω , be used for the subscript in molecular multiplets is based on the fact that when $S>\Lambda$, $\Lambda+\Sigma$ takes on negative as well as positive values. In such cases [none of which, however, have yet been observed] it would not suffice to specify Ω , since $\Omega=|\Lambda+\Sigma|$. In $^4\Pi$ states, for example, we should have $\Omega=\frac{1}{2}$ for both $^4\Pi_3$ and $^4\Pi_{-3}$.⁹ In this connection it may be well to remind the reader that in molecular multiplets, in contrast to many cases of atomic multiplets with $L>0$, the full multiplicity is always developed whenever $\Lambda>0$. For example, the molecular level $^4\Pi$ is quadruple (cf. reference 9) while the atomic 4P is only triple.

¹⁶ For subscripts which are multiples of $\frac{1}{2}$, either of the two forms such as $\frac{3}{2}$ or $1\frac{1}{2}$ may be used, but the second form ($1\frac{1}{2}$) is preferable for typographical reasons (cf. reference 2, p. 900).

It is recommended that these be distinguished, when one wishes, by calling them respectively Σ^+ and Σ^- states.^{16a} [The designations Σ^+ and Σ^- respectively correspond to Σ and Σ' of Wigner and Witmer.^{17,18}]

In the case of homonuclear molecules (molecules composed of atoms whose nuclei are identical in charge and mass), any electron state may be either "odd" or "even."¹⁹ An electron state of a homonuclear molecule is said to be *odd* if the *electronic factor* of ψ changes sign on reflection in the midpoint of the line joining the nuclei, *even*, if it does not change sign.^{19,19a} It is recommended that the odd or even character of an electron state, *when known*, and *if desired*, be indicated by a subscript at the right of the electronic term symbol. The subscripts *g* (German *gerade*) for even terms and *u* (German *ungerade*) for odd terms are recommended.²⁰ Examples, $^1\Sigma_g$, or $^1\Sigma_g^+$, or $^1\Sigma_g^-$, $^2\Sigma_u$;

^{16a} Corresponding to the frequently used empirical designations such as Π_b and Π_a (cf. Section VI, Fig. 2, etc.), theoretical designations such as Π^+ (even terms^{19a} when K is even) and Π^- (odd terms when K is even) might be introduced, in analogy to Σ^+ and Σ^- .

¹⁷ E. Wigner and E. E. Witmer, *Zeits. f. Physik*, **51**, 859, 1928. In Σ^+ states the rotational levels with even values of K are "even" or "positive," those with odd K are "odd" or "negative," while in Σ^- states these relations are reversed.^{19a}

¹⁸ Wigner and Witmer's use of Σ where Σ^+ is proposed here is obviously undesirable, since the symbol Σ is needed to imply *merely* $\Delta = 0$ in cases where one cannot, or does not wish to, decide between Σ^+ and Σ^- , as well as in general discussions. Wigner and Witmer's use of Σ' where Σ^- is proposed here is undesirable because of the frequent use of the prime ('), in the analysis of spectra, to denote the upper of two energy levels.

¹⁹ The use of "odd" and "even" in this sense was introduced by Hund. Cf. the useful summary by W. Weizel, *Zeits. f. Physik*, **54**, 324-6 (1929).

^{19a} The words even and odd are applied by Kronig, in a sense different from that used by Hund,¹⁹ to the *complete* ψ function of any molecule, homonuclear or heteronuclear; a molecular term is odd or even in this sense according as its ψ function does or does not change sign on reflection in the origin of coordinates; this definition is the same as that which holds for odd and even atomic terms. Instead of "even" and "odd" Wigner uses "positive" and "negative" for atomic terms, and Wigner and Witmer (l.c., Ref. 17) for molecular terms.

In speaking of molecular terms, the designations "even" and "odd" (which may be abbreviated *g* and *u*, as in Fig. 2) may be preferred to "positive" and "negative" on two grounds: (1) they were introduced earlier (R. de L. Kronig, *Zeits. f. Physik*, **50**, 351, 1928), and (2) they refer to the same properties which in atoms are generally described by "even" and "odd." But "positive" and "negative" (which may be abbreviated $+$ and $-$) may be preferred on other grounds: (1) they avoid possible confusion with the earlier-introduced and equally well-founded use of "even" and "odd" in another sense for electronic terms;^{19a} (2) they avoid the confusing situation that molecular levels with even, or with odd, K values may be either "even" or "odd." In Fig. 2 and elsewhere in this report, "even" and "odd" are used, but the writer now intends personally to use "positive" and "negative."

²⁰ In the report on line spectra (reference 2), it was suggested that a superscript^o (degree mark) always be used for odd terms, and *no* superscript for even terms. It may be that this precedent should be followed, although "odd" and "even" do not have just the same meaning here as in atoms. But this would hardly be feasible anyway in molecular spectra, since in some cases we do not yet *know* whether a term is even or odd. Further, there are many purposes for which the odd or even character is a matter of indifference, and it is desirable in such cases to be able to drop the superscript, without thereby implying that the term is even. The choice of *g* and *u* in preference to the English *e* (even) and *o* (odd) is based mainly on the fact that *e* is often used as a subscript for other purposes, as in E_e and r_e , while *o* is easily confused with zero.

The choice of the subscript position is governed by the fact that *g* and *u* are sometimes

${}^2\Pi_{3g}$; ${}^3\Pi_u$. [The designations Σ_g^+ , Σ_u^+ , Σ_g^- , Σ_u^- , Π_u , Π_g , Δ_g , Δ_u , etc. as here proposed, respectively correspond to Σ_+ , Σ_- , Σ'_+ , Σ'_- , Π_+ , Π_- , Δ_+ , Δ_- , etc. of Wigner and Witmer.]

The term symbols just recommended are of course not sufficient to identify completely the electronic state of a molecule. This purpose can be accomplished by the use of an identifying symbol of an empirical character, as for example A , B , X , a , etc.; or by the use of a symbol describing the electron configuration (cf. section IV, below.) *It is recommended* that such symbols be placed before the symbol giving S , Λ and Σ , as in the following examples: $A {}^3\Pi_2$; $X {}^1\Sigma$; $1s\sigma^2 2p\sigma 2s\sigma {}^3\Sigma$ (if the meaning is clear from the context, this last may be abbreviated to $2s\sigma {}^3\Sigma$ or $2s {}^3\Sigma$). These and similar designations can be adapted to the individual case, and varied to suit the need of experimentalist and theorist.

If one desires to express the relation of a molecular electronic state to the states of its atomic dissociation products, it is suggested that designations such as the following be used: $X {}^1\Sigma({}^2S+{}^2P)$. Here 2S and 2P represent the states of the two atoms. If desired, the electron configurations of atoms and molecule can also be given.

Some writers have used a superscript number, appended to the electronic term symbol, to indicate v . Example, ${}^3\Sigma^2$, for $v=2$. It is suggested that this practice be avoided if possible, and that simpler, although longer, expressions such as "the level $v=2$ of ${}^3\Sigma$ " be used. In case, however, a necessity is felt for including v in the term symbol, it is suggested that this be given as a superscript *in parentheses to indicate* that it represents an element foreign to the rest of the symbol. Examples, ${}^3\Sigma^{(2)}$; ${}^3\Sigma_g^{-(2)}$.

If one needs to give the rotational quantum number (K or J) as well as v , it may be given in parentheses as in the following example: ${}^3\Sigma^{+(1)}(10)$, for $v=1$, $K=10$.

IV. QUANTUM NUMBERS FOR INDIVIDUAL ELECTRONS; ELECTRON CONFIGURATIONS

The designation Λ was recommended above as the quantum number for the component, parallel to the electric axis, of the resultant orbital angular momentum of the entire electron system. The *designation λ is now recommended* [to replace the former designation i_{lr} or σ_{lr} or σ_{k_r}] for the corresponding quantum number for an *individual electron*.²¹ It is recommended further

needed for *individual electrons* (cf. Section IV below), as in σ_g , σ_u , π_g , etc., where the superscript position would lead to awkwardness in the symbols for electron configurations. For example, $\sigma_g^2\sigma_u^2\pi_u^4$ is much less awkward than $\sigma^{g2}\sigma^{u2}\pi^{u4}$. It is also preferable in such symbols as ${}^2\Sigma_g^+$, ${}^2\Sigma_u^{+(1)}$, etc. In cases such as ${}^2\Pi_{3g}$ it is not so good, but also not very bad, and furthermore, one is usually not interested in the $\frac{1}{2}$ and the g at the same time, so that one will usually write just ${}^2\Pi_{\frac{1}{2}}$ or else ${}^2\Pi_g$, depending on the nature of the discussion.

²¹ The quantization leading to the assignment of λ values for individual electrons is rigorous only to the extent that the interactions of the electrons with one another can be replaced by an axially symmetrical electric field. Ordinarily, however, the assignment of individual λ values in molecules should be about as justifiable as the assignment of individual l values in atoms.

that electrons having $\lambda = 0, 1, 2, 3, 4, 5, \dots$ be respectively *designated* $\sigma, \pi, \delta, \phi, \gamma, \eta, \dots$ electrons. [These were formerly named s, p, d, \dots electrons by the present writer, although not with the same meaning as s, p, d, \dots in atoms.]

Under some circumstances quantum numbers n, l , and s can also be assigned to the individual electrons in a molecule, just as to those in an atom. In Hund's case d these quantum numbers have practically the same meaning as in an atom (examples, excited orbits of series electron in H_2, He_2).²² Ordinarily, however, n and l are not at all rigorous quantum numbers and have a definite meaning only in terms of some ideal limiting case, such as that of the atom which would be obtained ("united-atom") if one could unite the two nuclei of the molecule.^{22,23} To designate the values of l in a molecule the symbols s, p, d, \dots are recommended for $l = 0, 1, 2$, just as in the case of an atom. When n, l , and λ are all to be indicated for an electron, symbols such as $2p\sigma, 3s\sigma, 3p\pi, 4d\sigma, \dots$ are recommended; the number represents n . [In the notation formerly used by the present writer, the equivalents of these symbols are $2s^p, 3s^s, 3p^p, 4s^d, \dots$ respectively.]²⁴ When several electrons ($1, 2, 3, \dots$) are present, their several values of n, l, λ can be indicated, if desired, by numerical subscripts, as $l_1, l_2, \dots, \lambda_1, \lambda_2$, etc.

The quantum number λ represents the projection of l on the electric axis of the molecule.⁷ Ordinarily any λ is considered a positive quantity, but in a molecule with several electrons some of the λ 's must be considered as having a negative sign. Λ is then the algebraic sum of the individual λ 's. Those individual λ 's whose direction is opposite to Λ are regarded as having a negative sign.

Even when the assignment of an l value to an electron has little meaning there is still, in *symmetrical molecules*, a definite distinction between *odd* and *even* states of an electron. Thus one may speak of $\sigma_g, \sigma_u, \pi_u, \pi_g, \dots$ etc. electrons. Insofar as an l can be assigned, an even value of l always gives an even type of electron (σ_g, π_g etc.), and an odd value of l an odd type.—In a similar way, the even or odd character of the resultant electron state of a symmetrical molecule is determined, like that of an atom, by the (*arithmetic*) sum of the individual l values. If this sum is even, the term is even (Σ_g, Π_g, \dots etc.), and conversely.

Often one may wish to indicate not the "united-atom" values of l and n for an electron, but the values of l and n which the electron would have if the molecule were separated into its atoms. For this purpose, symbols such as $\sigma(1s), \sigma_g(2p), \pi(2p)$, etc., are suggested. Here the symbol σ or π gives the

²² For the series electron in H_2 and He_2 , most of the orbits are large compared with the distance between the nuclei, so that "united-atom" conditions are closely approximated.

²³ In terms of spherical coordinates (r, θ, φ) as in the ideal limiting case of the "united-atom," l is defined as $n_\theta + n_\varphi$, where n_θ and n_φ are quantum numbers associated with θ and φ . In terms of elliptical coordinates (ξ, η, φ), as in another ideal limiting case where the electrons move under the influence of two point charges (as in H_2^+), l is defined as $n_\eta + n_\theta$ ($\eta = \text{const.}$ is a hyperboloid of revolution).

²⁴ The symbols $2s^p$ etc. were introduced by the present writer (Phy. Rev. **32**, 186, 1928); $2p\sigma$, etc. by F. Hund. (Zeits. f. Physik, **51**, 759, 1928).

value of λ for the electron in the molecule, while the symbol in parentheses describes the state of the electron as it would exist in one of the atoms on dissociation of the molecule.

Electron configurations. A rather complete description of the state of a molecule is possible if the term symbol, which gives the quantum numbers associated with the molecule as a whole, is preceded by a set of symbols giving the electron configuration. Examples: $1s\sigma^2 2p\sigma^2 2s\sigma^2 2p\pi^3 {}^2\Pi$; or more briefly, $\sigma^2\sigma^2\sigma^2\pi^3 {}^2\Pi$; or, if the molecule is symmetrical, $\sigma_g^2\sigma_u^2\sigma_g^2\pi_u^3 {}^2\Pi_u$. The electron configuration designations used here are similar to those used in line spectra. Such a symbol as $1s\sigma^2$ really means $(1s\sigma)^2$, i.e., it indicates the presence of two $1s\sigma$ electrons; while σ^2 indicates any two σ electrons of identical type (equivalent σ electrons). The order in which successive symbols are written is that of decreasing firmness of binding.—Such a symbol as $\sigma^2\sigma^2\sigma^2\pi^3$ rather than $1s\sigma^2 2p\sigma^2 2s\sigma^2 2p\pi^3$ is often to be preferred, since the assignment of definite n and l values is usually rather lacking in meaning. The symbol $\sigma^2\sigma^2\sigma^2\pi^3$ signifies the existence of three different kinds of σ electrons without attempting to describe them in detail.

V. SYMBOLS FOR MOLECULAR CONSTANTS

The energy E of a diatomic molecule is commonly written as a sum of three parts (for exact definitions, cf. Section VI):

$$E = E_e + E_v + E_r \quad (1)$$

Here E_e is the "electronic energy," E_v is the "vibrational energy," and E_r is the "rotational energy."

For the energy of a molecule in a singlet state²⁵ we had according to the old quantum theory (using, however, the new symbols v and J in place of n and j)²⁶

$$E = E_e + hc[\omega_0 v - x\omega_0 v^2 + y\omega_0 v^3 + \dots] + hc[B_v(J^2 + \text{const.}) + D_v J^4 + F_v J^6 + H_v J^8 + \dots] \quad (2)$$

Here the first expression following E_e represented E_v , the second E_r . In Eq. (2), we had

$$B_v = B_0 - \alpha v + \gamma v^2 + \dots, \text{ where } B_0 = h/8\pi^2 c \mu r_0^2 = h/8\pi^2 c I_0. \quad (3)$$

Also,

$$D_v = D_0 + \beta v + \dots, \text{ where } D_0 = -4B_0^3/\omega_0^2. \quad (4)$$

In Eqs. (2)–(4), the subscript zero attached to a coefficient implied that this coefficient corresponded to $v=0$. At the same time, since the energy of vibra-

²⁵ The "const." in $(J^2 + \text{const.})$ depends on the electronic motions (cf. R. S. Mulliken, ref. 5, Eq. (29)). Small constants should also be added to the terms in J^4 , etc.; and other small terms should be added.

²⁶ The notation used for the coefficients in Eqs. (2)–(4) etc. is mainly that which is now most usual. Instead of ω_0 one often finds ν_0 or ω^0 ; instead of D_v , $-\beta$. The designation $y\omega_0$ in Eq. (2) and γ in Eq. (3) are not in common use, but have been introduced here to supply an existing lack. No recommendation of this use of y and γ is intended here.

tion was supposed to be zero when $v=0$, it implied a molecule with stationary nuclei in a state of *equilibrium*. Thus $c\omega_0$ was supposed to represent the frequency of vibration for $v=0$, and so the limiting frequency for infinitesimal amplitudes. Similarly B_0 referred to $v=0$, and so supposedly to a molecule in equilibrium; and the quantities r_0 and I_0 calculated by means of Eqs. (3) likewise were supposed to correspond to a molecule in equilibrium.

According to the new quantum theory, however, Eqs. (2)–(4) must be replaced by equations of the following form:^{26a}

$$E = E_e + hc\left\{\omega_0\left(v + \frac{1}{2}\right) - x\omega_0\left(v + \frac{1}{2}\right)^2 + y\omega_0\left(v + \frac{1}{2}\right)^3 + \dots\right\} \\ + hc\left\{B_v\left[\left(J + \frac{1}{2}\right)^2 + \text{const.}\right] + D_v\left(J + \frac{1}{2}\right)^4 + \dots\right\} \quad (2a)$$

$$B_v = B_0 - \alpha\left(v + \frac{1}{2}\right) + \gamma\left(v + \frac{1}{2}\right)^2 + \dots, \text{ where } B_0 = h/8\pi^2 c\mu r_0^2 = h/8\pi^2 cI_0 \quad (3a)$$

$$D_v = D_0 + \beta\left(v + \frac{1}{2}\right) + \dots, \text{ where } D_0 = -4B_0^3/\omega_0^2. \quad (4a)$$

If one assumes the validity of Eqs. (2a)–(4a) one gets somewhat *different numerical values* for E_e , ω_0 , x , B_0 , r_0 , I_0 , etc. than if one assumes Eqs. (2)–(4). In the literature most of the recorded values are based on Eqs. (2)–(4), although in some recent articles Eqs. (2a)–(4a) have been used as a basis of calculation. Thus the same symbols are now being used in different articles in two different ways, with resulting confusion on the part of the reader.

To remedy this situation a *revision of nomenclature is suggested*, at least for discussions dealing with the analysis of band spectra, such that Eqs. (2a)–(4a) are replaced by the following Eqs. (2c)–(4c).^{26, 26a, 27, 28} At the same time, equations of the form of Eqs. (2)–(4), except for the substitution of $(J + \frac{1}{2})^2$ for J^2 , may usefully be retained (Eqs. 2b–4b).²⁹ Eqs. (2b)–(4b) represent the more useful form for the empirical description of spectra, Eqs. (2c)–(4c) for the analysis of the isotope effect and for the theoretical application of band spectrum data as in the construction of $U(r)$ curves (cf. second paragraph following).

$$E = E_0 + hc\left[\omega_0 v - x\omega_0 v^2 + y\omega_0 v^3 + \dots\right] \\ + hc\left\{B_v\left[\left(J + \frac{1}{2}\right)^2 + \text{const.}\right] + D_v\left(J + \frac{1}{2}\right)^4 + \dots\right\} \quad (2b)$$

$$B_v = B_0 - \alpha v + \gamma v^2 + \dots \quad (3b)$$

$$D_v = D_0 + \beta v^2 + \dots \quad (4b)$$

$$E = E_e + hc\left\{\omega_e\left(v + \frac{1}{2}\right) - x_e\omega_e\left(v + \frac{1}{2}\right)^2 + y_e\omega_e\left(v + \frac{1}{2}\right)^3 + \dots\right\} \\ + hc\left\{B_v\left[\left(J + \frac{1}{2}\right)^2 + \text{const.}\right] + D_v\left(J + \frac{1}{2}\right)^4 + F_v\left(J + \frac{1}{2}\right)^6 + \dots\right\} \quad (2c)$$

^{26a} Although the form $(J + \frac{1}{2})^2$ is used here, it is immaterial to the present discussion whether this or the rival form $J(J+1)$ is used.

²⁷ The use of the symbol E for energy, as in E and E_0 , although it seems desirable, is not definitely included in the recommendations made here.

²⁸ The coefficients of Eqs. (2b)–(4b) are related to those of Eqs. (2c)–(4c) as follows: E_0 (Eq. 2b) = E_e (Eq. 2c) + $hc\left[\frac{1}{2}\omega_e - (1/4)x_e\omega_e + (1/8)y_e\omega_e + \dots\right]$; $\omega_0 = \omega_e\left[1 - x_e + (3/4)y_e + \dots\right]$; $x\omega_0 = \omega_e[x_e - (3/2)y_e + \dots]$; $y\omega_0 = \omega_e(y_e + \dots)$; etc.

²⁹ The quantities r_0 and I_0 calculated as in Eq. (3) are no longer of much interest, since they are not empirical coefficients, nor have they the theoretical importance of r_e and I_e .

$$B_v = B_e - \alpha_e(v + \frac{1}{2}) + \gamma_e(v + \frac{1}{2})^2 + \dots, \text{ where} \quad (3c)$$

$$B_e = h/8\pi^2 c \mu r_e^2 = h/8\pi^2 c I_e$$

$$D_v = D_e + \beta_e(v + \frac{1}{2}) + \dots, \text{ where } D_e = -4B_e^3/\omega_e^2. \quad (4c)$$

The coefficients ω_e , B_e , etc. and the quantities I_e and r_e (and E_e) refer to a molecule with stationary nuclei in equilibrium; such a molecule, however, in contrast to the state of affairs in the old quantum theory, would *not* at the same time have $v=0$. B_0 , D_0 , E_0 , etc., refer to a molecule with $v=0$.²⁹

For the *energy of dissociation* of a molecule, the symbol D has been widely adopted. To be accurate, one must distinguish D_e , the energy of dissociation for the imaginary case of a molecule with nuclei stationary at the distance r_e ; and D_0 or D , the energy of dissociation from the actual lowest energy level of the molecule ($v=0$). The values of D for various states of a molecule may be conveniently distinguished by putting identifying designations in parentheses, as $D(X)$ or $D(X^1\Sigma)$; $D(A^3\Pi)$; etc. In all cases the symbol D should stand for the energy of dissociation alone, and should not include, in the case of an excited electron state, the energy of excitation.

If the energy of a molecule in a definite electron state, with nuclei held stationary, is expressed as a function $U(r)$ of the distance between the nuclei, then $E_e \equiv U(r_e)$, while the dissociation energy $D_e \equiv U(\infty) - U(r_e)$. Also, $4\pi^2 \mu c^2 \omega_e^2 = (d^2 U/dr^2)_{r=r_e}$.

It may eventually be worth while to discard the heterogeneous and cumbersome set of symbols B_v , D_v , α , β , ω_e , $x_e \omega_e$, etc.²⁸ in favor of a simpler set. If, or when, this is done, the double use of D for heat of dissociation and for the coefficient of $(J+\frac{1}{2})^4$ might well be done away with. One might perhaps use d_v instead of D_v in the E_r expression (also, for consistency, f_v instead of F_v and possibly also b_v instead of B_v). This would, however, interfere with the possible future use of a , b , c , \dots in place of ω_e , $x_e \omega_e$, $y_e \omega_e \dots$ in Eq. (2c), or perhaps better in place of ω_0 , $x\omega_0$, $y\omega_0$, \dots in Eq. (2b); a , b , \dots have already often been used in this way.

VI. DESCRIPTION AND ANALYSIS OF SPECTRA

Term designations. In the analysis of spectra, one is usually concerned with the determination of energy values (E) or term-values (E/hc) through the use of the relation $\nu = (E' - E'')/hc$. The prime (') and double prime (') are used merely to indicate that $E' > E''$.²⁷ It is recommended that the *prime* and *double prime* be always used in a similar manner when one wishes to distinguish the *upper* and *lower* of two energy levels involved in the production of the lines of a band spectrum, and that this method be applied to all quantum numbers and coefficients pertaining to these energy levels. In discussing spectra, it is best to avoid where possible the expressions "initial" and "final" levels, since in terms of E' and E'' these have opposite meanings in absorption and emission spectra.

In the analysis of spectra, it is convenient to have a symbol to denote term-values. It is suggested that T be used for this purpose ($T \equiv E/hc$).³⁰ For

³⁰ The symbol F has sometimes been used for E/hc . (The present writer has in fact used this, and also F^{el} for E_e/hc , F^v for E_v/hc , and F^r for E_r/hc). But F has *usually* been used

the upper and lower levels involved in the production of a spectrum line, T' and T'' would be used.

In dealing with the analysis of a particular spectrum, the symbol T , followed by the rotational quantum number designation in parentheses, also the vibrational quantum number, if desired, as a superscript in parentheses, is suggested as a convenient symbol. Examples: $T(8)$, $T^{(2)}(8)$; also, $T_1(8\frac{1}{2})$, $T_{2a}(7\frac{1}{2})$, $T_a(9)$, etc., using numerical and literal subscripts in a manner to be discussed below in connection with the symbol F (cf. paragraphs following Eq. (7)).

For some purposes it is extremely convenient to have separate symbols for "electronic terms" (E_e/hc), "vibrational terms" (E_v/hc), and "rotational terms" (E_r/hc). It is suggested that the symbols G and F be used for vibrational and rotational terms respectively.³⁰ For electronic terms the symbol T_e is suggested. Thus we have, paralleling Eq. (1),

$$T = T_e + G + F. \quad (5)$$

Definitions of electronic, vibrational, and rotational energies and terms. It is important to define with some care the quantities F , G , and T_e , or the corresponding quantities E_r , E_v , and E_e . The following definitions appear to be unambiguous.

(1) The energy E_r is the difference between the energy of the actual molecule and that of an idealized molecule obtained by the following imaginary process: the rotation of the nuclei is gradually stopped without placing any new constraint on the vibration of the nuclei or on the electron motions, in such a way as might be realized by gradually (i.e. adiabatically) coupling an infinite moment of inertia to the axis of rotation of the molecule. In Eqs. (2c)–(4c), B_v and all the coefficients of powers of $(J+\frac{1}{2})^2$ then go to zero.

(2) The energy E_v is the difference between the energy of a molecule idealized just to the extent of making $E_r=0$ and the energy of a further idealized molecule obtained by the following imaginary process: the vibration of the nuclei is gradually stopped without placing any new constraint on the electron motions, in a way such as might be realized by leaving the charges of the nuclei unchanged but gradually increasing the masses until they are infinite. In Eqs. (2b)–(4b), ω_e and all the coefficients of powers of $(v+\frac{1}{2})$ then go to zero.

(3) The energy E_e is the total internal energy of a molecule in a definite electronic state with the nuclei stationary (this condition may be realized in imagination by making the masses infinite) at their equilibrium distance (r_e) apart. E_e consists of (a) kinetic energy of the electrons, plus (b) their potential energy with respect to the nuclei and to one another, plus (c) the mutual potential energy of repulsion of the two nuclei. As was mentioned above, $E_e \equiv U(r_e)$.

with the meaning E_r/hc , and this usage is therefore recommended here (cf. Eq. (5)). The use of T for E/hc (or for $-E/hc$, measured from an arbitrary zero of energy at ionization) has been frequent in the field of line spectra. The use of G for E_v/hc (cf. Eq. (5) and ref. 38) was suggested by Birge and recommended in the National Research Council Report on Molecular Spectra, but this recommendation has not been widely followed.

Rotational term differences. In the analysis of band spectra, it is customary to use such designations as $\Delta F(J)$, $\Delta_1 F(J)$, $\Delta_2 F(J)$ for the difference between two rotational terms differing only in the value of J . [Formerly Δf and ΔF were often used to distinguish these term intervals respectively for the upper and lower of the two electron levels involved, but it is recommended that this distinction be made only by the use of (') and (''), as in $\Delta F'$, $\Delta F''$].

It is recommended that in designating rotational term intervals, the forms which are defined in the following equations be used:^{31,32}

$$\Delta_1 F(J + \tfrac{1}{2}) = F(J + 1) - F(J) \quad (6)$$

$$\Delta_2 F(J) = F(J + 1) - F(J - 1). \quad (7)$$

Examples,

$$\Delta_1 F(3\frac{1}{2}) = F(4) - F(3); \quad \Delta_2 F(4) = F(5) - F(3).$$

In all states with $\Lambda > 0$ there are, for a given value of Σ and of J in case *a*, or of K and of J in case *b*, two rotational levels (cf. Fig. 2). (These are usually

Fig. 2. Λ -type doublets for the case $S=0$, $\Lambda=1$. The order shown for the g and u levels represents only one of two possibilities; the case in which 1(g) lies above 1(u), 2(u) above 2(g), and so on, is the other (g and u respectively stand for even and odd^{19a}). There is also no fixed rule as to the relative position of a and b levels; nor is there any fixed rule for correlating the a , b , and the g , u descriptions (cf. references 35, 36, 19a).

very close together, but separate widely on approach to case *d*). This doubling may be called *Λ -type doubling* because it occurs if, and only if, $\Lambda > 0$. [It was formerly, but less correctly, called " σ -type doubling," where " σ " is a former designation for our present Ω .³³] It is suggested that, in each

³¹ $\Delta_1 F(J + \frac{1}{2})$ and $\Delta_2 F(J)$ may be read as "delta one $FJ + \frac{1}{2}$ " and "delta two FJ ."

³² $\Delta_1 F(J + \frac{1}{2})$ is commonly denoted by $\Delta_1 F(J)$, but the use of the symbol $\Delta_1 F(J + \frac{1}{2})$ as in Eq. (6) seems preferable. In practise, $\Delta_1 F(J + \frac{1}{2})$ is much less important than $\Delta_2 F(J)$, since $\Delta_1 F(J + \frac{1}{2})$ cannot be directly and exactly evaluated from the analysis of a spectrum; instead one usually obtains $F_a(J+1) - F_b(J)$, or $F_b(J+1) - F_a(J)$.

³³ The name " σ -type-doubling" was given by the writer before Hund's development of the theory of molecular electronic states, and was based on the idea that this type of doubling occurs whenever $\sigma > 0$ [in the present symbols, whenever $\Omega > 0$]. Later Hund showed that this doubling is to be expected, not whenever $\Omega > 0$ but whenever $\Lambda > 0$. Usually $\Lambda > 0$ and $\Omega > 0$

rotational doublet of this kind, the component levels be distinguished as a and b sublevels,³⁴ and that the term values be distinguished by corresponding subscripts, as, $T_a^{(v)}(J)$, $T_b^{(v)}(J)$, $F_a(J)$, $F_b(J)$.^{16a, 35, 36} For rotational term differences, we have then $\Delta_2 F_a(J)$, $\Delta_2 F_b(J)$, \dots etc.

In case b , it is necessary to provide a means of indicating both K and J . The writer^{35a} suggested the use of the symbols F_1 , F_2 ; $\Delta_1 F_1$, $\Delta_1 F_2$; $\Delta_2 F_1$, $\Delta_2 F_2$ for case b with $S = \frac{1}{2}$, where F_1 refers to the terms with $J-K = +\frac{1}{2}$ and F_2 to $J-K = -\frac{1}{2}$. For $S = 1$, the suggested symbols were F_1 , F_2 , F_3 , for $J-K = +1$, 0 , -1 respectively. These suggestions are now renewed,^{36b} with the added suggestion that this use of numerical subscripts be applied both to the rotational terms F and to the complete terms T ; when $\Lambda > 0$, a and b subscripts are needed in addition to the numerical subscripts. Examples, $T_1^{(v)}(J)$; $T_{2a}^{(v)}(J)$; $F_{2b}(J)$; $\Delta_2 F_1(J)$; $\Delta_2 F_{1a}(J)$; $\Delta_2 F_{2b}(J)$; $\Delta_2 F_{2a}(J)$, etc.; specifically, $\Delta_2 F_{1a}(5\frac{1}{2})$ would mean $F_{1a}(6\frac{1}{2}) - F_{1a}(4\frac{1}{2})$, with the K values 6 and 4. Sometimes when K is the important rotational quantum number, J is lacking in significance (case b' , cf. Section II above). In such a case, one naturally will use such forms as $\Delta_2 F(K)$, $\Delta_2 F_a(K)$. Also when $S = 0$, so that $J \equiv K$, one may use K instead of J as the argument of a ΔF expression.

Vibrational term differences. It is suggested that in designating vibrational term differences, the forms which are defined in the following equations be used.³⁷

$$\Delta G(v + \frac{1}{2}) = G(v + 1) - G(v) \quad (6)$$

$$\Delta^2 G(v) [\equiv \Delta G(v + \frac{1}{2}) - \Delta G(v - \frac{1}{2})] = G(v + 1) - 2G(v) + G(v - 1). \quad (7)$$

go hand in hand. A familiar exception is ${}^3\Pi_0(\Lambda = 1, \Omega = 0)$. Experimentally this shows Λ -type doubling as predicted by Hund.

³⁴ The use of the designations A and B was suggested by the present writer (Phys. Rev., 30, 791, 1928). Some people have followed this suggestion, others have substituted a and b . The difference is not essential, but a and b seem to be preferred by the majority. (These designations have nothing to do with Hund's cases a and b).

³⁵ The designations a and b are essentially temporary empirical labels, and have no definite relation to any designations of theoretical significance (but cf. ref. 36). For two formal schemes for choosing which levels to call a and which to call b , cf. (1) R. S. Mulliken, Phys. Rev. 28, 1205 (1926) and (2) R. S. Mulliken, Phys. Rev. 30, 791 (1927). Some writers follow the first scheme, more the second. Both schemes lead to the same use of the labels a and b in the case of Π states, but give opposite labellings in the cases of Σ and of Δ states.

³⁶ The division into a and b levels is related to the theoretical division (cf. Ref. 19a and Wigner and Witmer, l.c. Ref. 17) of all molecular terms into even or positive and odd or negative terms. In the case of Π states, if either of the methods of labelling mentioned in ref. 36 is followed, the result is usually that in the b set of sub-levels, the even-numbered levels are even and the odd-numbered are odd; in the a set of sub-levels, the relations are always the reverse of those in the b set. The nature of the correlation between a and b and even and odd levels is illustrated in Fig. 2. For the case of Σ levels, cf. reference 18. In the case of Δ , Φ , \dots levels, the relations are of the same type as in Π levels.

^{36a} Cf. R. S. Mulliken, Phys. Rev. 30, 788 (1927).

^{36b} A more logical method would be to use the values of $J-K$ as subscripts, as in $F_{+\frac{1}{2}}(J)$, $F_{-\frac{1}{2}}(J)$, $\Delta_2 F_{+\frac{1}{2}}(J)$, $Q_{-\frac{1}{2}-\frac{1}{2}}(J)$, instead of $F_1(J)$, $F_{2a}(J)$, $\Delta_2 F_1(J)$, $Q_{12}(J)$. But since the present notation is simple and reasonably satisfactory, it does not seem wise in this report definitely to suggest a change.

³⁷ $\Delta G(v + \frac{1}{2})$ and $\Delta^2 G(v)$ may be respectively read as "delta $Gv + \frac{1}{2}$ " and "delta second Gv ."

Examples, $\Delta G(3\frac{1}{2}) = G(4) - G(3)$; $\Delta^2 G(4) = \Delta G(4\frac{1}{2}) - \Delta G(3\frac{1}{2}) = G(5) - 2G(4) + G(3)$. It will be seen that the argument of ΔG is always a half-integer midway between the v values (always integers) of two energy levels, while the argument of $\Delta^2 G$ is always an integer. [$\Delta G(v + \frac{1}{2})$ as here used is synonymous with Birge's $\Delta G_{v+\frac{1}{2}}$ and with $\omega_{v+\frac{1}{2}}$ as introduced by Birge and Sponer.³⁸]

Band and system origins. In describing a band spectrum, it is convenient to consider the frequency of each line as a sum of three parts, just as it is convenient to consider the energy and the term-value each as a sum of three parts (cf. Eqs. (1), (5)). Thus for the wave number ν we may write³⁹

$$\nu = T' - T'' = (T_e' - T_e'') + (G' - G'') + (F' - F'') = \nu_e + \nu_v + \nu_r. \quad (8)$$

The concepts of the "origin" of a band and of a band system are frequently used in theoretical discussions. These can be unambiguously defined as follows.³⁹

System-origin: $\nu = \nu_e$

Band-origin: $\nu = \nu_e + \nu_v$.

These definitions do not in general correspond to wave-number positions which are of importance in the analysis of band spectra, except in the study of the isotope effect. Band and system origins are discussed here only in order to remove possible misconceptions as to their meaning.

In *simple types* of bands, an equation for the band lines can often be given in the form

$$\nu = \nu_0 + aM + bM^2 + \dots, \quad (9)$$

where M is a parameter which takes on positive and negative integral or half-integral values, related to values of K'' or J'' . The line given by $\nu = \nu_0$, and often other lines, are ordinarily missing. In the simplest cases, ν_0 is approximately the same as $\nu_e + \nu_v$, but the agreement is never exact if we use accurate expressions for E_e , E_v , and E_r ; and the difference between ν_0 and $\nu_e + \nu_v$ varies from one type of band to another. The term "band-origin" is often loosely applied to ν_0 , but it is evident that this usage is inaccurate and tends to produce confusion.

In a system of bands, the band origins can be expressed by the equation

$$\begin{aligned} \nu_e + \nu_v = \nu_e + \omega_e'(v' + \tfrac{1}{2}) - \omega_e''(v'' + \tfrac{1}{2}) \\ - x_e'\omega_e'(v' + \tfrac{1}{2})^2 + x_e''\omega_e''(v'' + \tfrac{1}{2})^2 + \dots \end{aligned} \quad (10)$$

The origin of the 0, 0 band (obtained by putting $v' = 0$, $v'' = 0$ in Eq. 10) obviously does not coincide with the origin of the band system ($\nu = \nu_e$). If

³⁸ For the original proposal to use ΔG , cf. the National Research Council Report on Molecular Spectra, p. 123, Eq. (76). (In Eq. (76) the old symbol n appears instead of v .) In regard to $\omega_{v+\frac{1}{2}}$ cf. R. T. Birge and H. Sponer, Phys. Rev. 28, 259, (1926).

³⁹ Where ν_v , ν_r are used here, other designations such as ν_n , ν_m are frequently used. No definite recommendation of ν_e , ν_v , and ν_r is intended here, although they are preferred by the present writer. It is pretty obvious, however, that ν_n and ν_m should be dropped, since their subscripts are the now discarded symbols n and m formerly used for the vibrational and rotational quantum numbers.

the old quantum theory formula for E_v (cf. Eq. (2)) were correct, the system-origin *would* coincide with the origin of the 0, 0 band. In existing tables of band spectrum data, based on the old quantum theory formulation, the origin, or even the ν_0 position, of the 0, 0 band is in fact commonly referred to as the system-origin.³⁹

Designations for band systems and bands. For designating a transition between two electronic states, it is suggested that the following forms be used: ${}^2\Pi \rightarrow {}^2\Sigma$ for emission bands (to be read " ${}^2\Pi$ to ${}^2\Sigma$ "); ${}^2\Pi \leftarrow {}^2\Sigma$ for absorption bands (this might be read " ${}^2\Pi$ from ${}^2\Sigma$ "); and simply ${}^2\Pi$, ${}^2\Sigma$ in general discussions. It is recommended that the equivalent form ${}^2\Sigma - {}^2\Pi$, which is analogous to atomic symbolism such as $1s - 2p$, be abandoned.⁴⁰ In the suggested symbols, the *first mentioned* (here ${}^2\Pi$) always refers to the state of higher energy.

In indicating the two vibrational levels concerned in the production of a particular band, one speaks of the (0, 3) band, the (5, 2) band, and so on, where the first number refers to v' , the second to v'' . Usually the parentheses can safely be dropped, so that one can write "the 0, 3 band," and so on.

Designations for band-lines. The lines of a band can always be divided into one or more series ("branches"). For all the lines in one branch, $J' - J''$ (also $K' - K''$ in case *b*) has a constant value. *It is recommended* that the symbols *O*, *P*, *Q*, *R*, *S* be used, in a way now to be described, to denote various types of branches. In case *a*, we define

$$\begin{aligned} O(J) &= T'(J-2) - T''(J) = \nu_e + \nu_v + F'(J-2) - F''(J) \\ P(J) &= T'(J-1) - T''(J) = \nu_e + \nu_v + F'(J-1) - F''(J) \\ Q(J) &= T'(J) - T''(J) = \nu_e + \nu_v + F'(J) - F''(J) \\ R(J) &= T'(J+1) - T''(J) = \nu_e + \nu_v + F'(J+1) - F''(J) \\ S(J) &= T'(J+2) - T''(J) = \nu_e + \nu_v + F'(J+2) - F''(J) \end{aligned}$$

In these symbols, the usual arbitrary convention has been adopted of *using the value of J''* , rather than that of J' or of $\frac{1}{2}(J' + J'')$, *as the argument*, but at the same time *substituting the symbol J for the symbol J''* for the sake of brevity. *It is recommended* that, to avoid confusion, the convention of using the value of J'' as argument be uniformly followed.

Branches $O(J)$ and $S(J)$ ordinarily exist only in Raman spectra, and there only in the form

$$\nu = \nu_{exc} \mp [O(J) \text{ or } S(J)].$$

Here ν_{exc} is the wave number of the exciting line; in $O(J)$ or $S(J)$, ν_e is zero in the cases usually investigated (vibration-rotation Raman bands), or ν_e and ν_v are both zero and at the same time we have only $S(J)$, not $O(J)$ (pure rotation Raman bands).

When, in case *b*, the fine structure corresponding to different values of $J - K$ is unresolved (case *b'*, cf. Section III), or narrow, one will naturally

⁴⁰ The form ${}^2\Sigma - {}^2\Pi$ is really sensible only in case each term is a member of a series converging to a known limit from which the term can be *measured downwards*. Except in H_2 and He_2 such series are not known for molecular terms, and the use of the corresponding notation has no point. Even in atomic spectra, its usefulness is limited to the simplest types of series spectra.

define and use $O(K), P(K), \dots$, in analogy to $O(J), P(J), \dots$, of case a . For example, in a ${}^2\Sigma, {}^2\Sigma$ transition, one has a branch $P(K)$ and a branch $R(K)$, each line of each branch being a usually narrow, often unresolved, doublet.⁴¹ Also when $S=0$, so that $J=K$, one may use K instead of J as argument.

In cases where both ΔK and ΔJ are important, it is necessary to designate both. For this purpose symbols such as $Q_{21}(J), R_{12}(J)$, etc. are suggested, in which J'' (written as J) is used as argument in the usual manner, and in which the numerical subscripts indicate values of $J-K$. It was suggested above that the rotational term designations F_1, F_2, F_3, \dots , be used in case b for $J=K+S, K+S-1, \dots, |K-S|$. Similarly,^{3, b} one may speak of branches $Q_{21}(J), R_{11}(J), Q_{22}(J), Q_{12}(J)$, etc., where the first numerical subscript refers to the upper energy level, the second to the lower. (Symbols such as $R_{11}(J)$ and $Q_{22}(J)$ can ordinarily be abbreviated to $R_1(J)$ and $Q_2(J)$.) For example, $Q_{21}(5\frac{1}{2})$ means $\nu_e + \nu_v + F_2'(5\frac{1}{2}) - F_1''(5\frac{1}{2})$, or, more briefly expressed, $T_2'(5\frac{1}{2}) - T_1''(5\frac{1}{2})$; here $K'=6, J'=5\frac{1}{2}, K''=5, J''=5\frac{1}{2}$, so that $K'-K''=+1$, while $J'-J''=0$. This notation is incomplete, however, until designations are added to indicate the a or b character of the rotational levels involved. When this is included, we have symbols such as $Q_{2a1a}(5\frac{1}{2}), Q_{2b1b}(5\frac{1}{2}), R_{1a1a}(J), R_{1b1a}(J), Q_{2b1b}(J)$, and $Q_{2a2a}(4\frac{1}{2})$ or more briefly $Q_2(4\frac{1}{2})$. If Λ' or Λ'' is zero, the a or b subscripts can be omitted.³⁶ The notation just suggested can be made more explicit by the addition of a superscript symbol to indicate $K'-K''$; examples, ${}^R Q_{2a1a}(5\frac{1}{2}), {}^R R_{1a1a}(J)$. The added superscript is, however, not necessary, since the value of $K'-K''$ is already implied in the remainder of the symbol. For a more detailed discussion of this notation, references 35 and 36 may be consulted.

In the analysis of band spectra, temporary designations for band lines are sometimes needed before the true J or K values involved are known. It is recommended that in such cases the lines and branches be designated and numbered in some way that will not be confused with approved theoretically significant designations. For example, one might use $X(m), Y(m), Z(m)$, etc.; or if ΔJ or ΔK is known, but the correct numbering is uncertain, $P(m), R(m)$, etc.; or $P_\alpha(m), P_\beta(m), R_\gamma(m), R_\delta(m)$, etc. The parameter m could be given values 1, 2, 3, \dots .

CONCLUSION

In Table I some of the most important changes recommended or suggested here are summarized.

TABLE I. Some new designations and some of their older equivalents.

New	Old	New	Old
v	n	λ	$i_{l\tau}, \sigma_{l\tau}, \sigma_{k\tau}$
J	j, m , etc.	$\sigma, \pi, \delta, \dots$	s, p, d, \dots
M	(magnetic quantum number)	$\{2p\sigma, 3s\sigma, 3p\pi, 3d\sigma, \text{etc.}\}$	$2s^p, 3s^s, 3p^p, 4s^d, \text{etc.}$
Λ	i_l, σ_k, σ_l	$T; T_e; G$	$E/hc; E_e/hc; E_v/hc$
Σ	i_s, σ_s, X	Λ -type doubling	σ -type doubling
Ω	i, σ	${}^2\Pi \rightarrow {}^2\Sigma$, or ${}^2\Pi, {}^2\Sigma$; etc.	${}^2\Sigma - {}^2\Pi$, etc.
K	p_l, j_k	Σ^+, Σ^-	Σ, Σ'
$\Sigma, \Pi, \Delta, \dots$	S, P, D, \dots	$\Sigma_u, \Sigma_u, \Pi_u, \Pi_g$, etc.	

⁴¹ Strictly, each line except the first is a triplet (cf. R. S. Mulliken, Phys. Rev. 30, 138, 1927).

Among those who have expressed approval of the recommendations and suggestions made in this report (except for possible minor reservations) are the following: H. S. Allen, G. M. Almy, E. Bengttson, R. T. Birge, A. Christy, E. U. Condon, F. H. Crawford, W. E. Curtis, D. M. Dennison, G. H. Dieke, R. Fortrat, A. Harvey, W. Heitler, G. Herzberg, E. L. Hill, E. Hulthén, F. Hund, F. A. Jenkins, W. Jevons, R. C. Johnson, J. Kaplan, E. C. Kemble, R. de L. Kronig, J. E. Lennard-Jones, F. London, F. W. Loomis, J. C. McLennan, R. Mecke, P. M. Morse, O. Oldenberg, R. W. B. Pearse, F. Rasetti, Lord Rayleigh, O. W. Richardson, B. Rosen, E. C. G. Stueckelberg, T. Takamine, H. C. Urey, J. H. Van Vleck, W. W. Watson, W. Weizel, E. Wigner, E. E. Witmer. The writer wishes to express his sincere thanks to these and others for their contributions in the way of criticisms, suggestions, and expressions of opinion. These form the basis of the present report. He is particularly indebted to Professors R. T. Birge and F. Hund for their very active cooperation and support.

THE APPLICATION OF THE FERMI-THOMAS STATISTICAL MODEL TO THE CALCULATION OF POTENTIAL DISTRIBUTION IN POSITIVE IONS

By EDWARD B. BAKER

DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received June 26, 1930)

ABSTRACT

The statistical method of Fermi and Thomas of calculating atomic potential distributions has been extended to include positive ions. A table of potentials for any positive ion is given. The results have been applied to the calculation of (a) ionic radii, (b) successive ionization potentials, (c) deviations from the Mosely law in optical spectra.

I. THE THEORY

FERMI¹ and Thomas² have considered the electrons in a neutral atom as a completely degenerate electron gas under the influence of the Coulomb field of the nucleus. Assuming radial symmetry, and using Poisson's equation, the Fermi-Dirac statistics permitted a calculation of the distribution of potential for neutral atoms. The present work provides a generalization of the method to include all positive ions also.

Fermi and Thomas obtained the differential equation

$$\frac{1}{r} \frac{d}{dr} \left(\frac{1}{r} \frac{dv}{dr} \right) = -4\pi\rho = \frac{2^{13/2}\pi^2 m^{3/2} e^{5/2}}{3h^3} v^{3/2} \quad (1)$$

with the boundary conditions

$$v \sim Ze/r \text{ near } r = 0, \text{ or } \lim_{r \rightarrow 0} vr = Ze \quad (2.0)$$

$$v(\infty) = 0 \quad (2.1)$$

which determine the solution for the neutral atom uniquely. The additional condition

$$\int \rho d\tau = -Ze \quad (3)$$

is simultaneously satisfied.

Introducing dimensionless variables

$$\psi = v/\gamma; \quad \gamma = \frac{2^{13/3}\pi^{4/3}me^3Z^{4/3}}{3^{2/3}h^2} \quad (4)$$

¹ E. Fermi, Zeits. f. Physik **48**, 73 (1928).

² L. H. Thomas, Proc. Camb. Phil. Soc. **23**, 542 (1927).

and

$$x = r/\mu; \quad \mu = \frac{3^{2/3} \hbar^2}{2^{13/3} \pi^{4/3} m e^2 Z^{1/3}}$$

then Eq. (1) becomes

$$\frac{d^2\psi}{dx^2} + \frac{2}{x} \frac{d\psi}{dx} = \psi^{3/2} \quad (5)$$

Substituting $\phi = \psi x$, we have

$$\phi'' = \frac{\phi^{3/2}}{x^{1/2}} \quad (6)$$

and Eqs. (2) and (3) become

$$\phi(0) = 1 \quad (7)$$

$$\phi(\infty) = 0 \quad (7.1)$$

and

$$\int_0^\infty \phi^{3/2}(x)^{1/2} dx = 1. \quad (8)$$

For the positive ion having z electrons and the atomic number Z , which we shall call an ion of order σ ($\sigma = z/Z$), we have, in place of Eq. (3),

$$\int \rho d\tau = -ze \quad (9)$$

and, in place of Eq. (8),

$$\int_0^{x_m} \phi^{3/2} x^{1/2} dx = z/Z = \sigma. \quad (10)$$

Since Eq. (9) is not fulfilled by the former solution, it follows that the boundary condition, Eq. (2.1), must be modified, since Eq. (2.0) must remain the same. A suggestion of how this is to be done may be obtained by a comparison of Eq. (5) with the equations

$$\frac{d^2\psi}{dx^2} + \frac{2}{x} \frac{d\psi}{dx} = -\psi^n \quad (11)$$

which have been extensively studied by Emden³ in connection with the distribution of matter in polytropic gas spheres. Emden found that for certain values of n , and certain boundary conditions, there are solutions of Eqs. (11) describing gas spheres of *finite* radius. This suggests that Eq. (3) may also have such solutions if the boundary conditions are modified.

Fermi⁴ and Razetti⁵ have used the approximate potential

$$v = -\frac{e}{r} \left[1 + (Z-1)\phi\left(\frac{r}{\mu}\right) \right] \quad (12)$$

³ Emden, "Gaskugeln," Leipzig, 1907.

⁴ E. Fermi, Zeits. f. Physik 49, 550 (1928).

⁵ F. Razetti, Zeits. f. Physik 49, 546 (1928).

(where μ is evaluated for $Z-1$), for a singly ionized atom. This is obtained by considering the ion of nuclear charge Z as a neutral atom of nuclear charge $Z-1$ plus an extra proton in the nucleus. This approximation neglects the "packing effect" that the added proton will have upon the electron cloud. It is not possible to generalize this result for much higher ionizations, for then the neglect of the packing effect becomes serious. The present method is designed to remove this difficulty.⁶

We propose a model of the positive ion having a finite radius x_m , beyond which the charge density is zero. The solution ϕ_σ of Eq. (6), representing a positive ion of order σ , must obey the boundary condition

$$\phi_\sigma(x_m) = \phi_{\sigma m} = 1 - \sigma = 1 - z/Z \quad (13)$$

instead of Eq. (7.1). We find that ϕ_σ then fulfills the extra condition of Eq. (10). For the neutral atom $x_m = \infty$, Eq. (13) reduces to Eq. (7.1), and Eq. (10) reduces to Eq. (8), as required.

Fig. 1.

In Fig. 1 are displayed the possible forms the solution of Eq. (6) may take if the boundary condition of Eq. (7.0) is satisfied. The curve ϕ_1 is the only solution for which $\phi(\infty) = 0$, and is that already obtained for the neutral

⁶ The two dimensional analogue of Eq. (5) is

$$\frac{d^2\psi}{dx^2} + \frac{1}{x} \frac{d\psi}{dx} = \psi$$

the solution of which is any cylinder function $Z_0(ix)$. The only cylinder function which has the required logarithmic behavior for $x=0$, and which vanishes for $x=\infty$, is the Hankel function of the first kind $H_0^{(1)}(ix)$. As this function becomes asymptotically equal to $e^{-x}/x^{1/2}$, it can only represent a neutral two dimensional atom. The corresponding fact is true for Eq. (5); there is no solution of Eq. (5) which satisfies the conditions of Eqs. (2.0) and (2.1) other than the one obtained by Thomas and Fermi for neutral atoms. This can also be shown by a direct method of inequalities. This remarkable property of Eq. (5) made necessary the linking up of two solutions as described above.

atom by Fermi and Thomas. For this solution we have found the starting slope $\phi_1'(0) = -B_1 = -1.588558$.

Since the differential equation is of the second order, a particular value of the initial slope $-B_\sigma$ at $x=0$ uniquely determines a single solution passing

Fig. 2.

Fig. 3.

through $\phi=1$, $x=0$. All solutions with $0 > -B_\sigma > -\infty$ are single valued in ϕ , and no two cross each other.

All solutions with $0 > -B_\sigma > -B_1$ have each a single minimum, the coordinates of which $(\phi_{\sigma m}, x_m)$ are monotonous functions of B_σ (see Fig. 2), so that

the locus of minima (see Fig. 3) is monotonous in both x and ϕ . The ordinates at the minimum range from $\phi_{1m}=0$ to $\phi_{\sigma m}=1$, for values of B_σ from B_1 to B_0 respectively. These solutions describe any positive ion ($0 \leq \sigma \leq 1$) as far as the minimum, which is the boundary of the ion; beyond that point the Coulomb field requires a straight line parallel to $\phi=0$, and a distance $1-\sigma$ above it, corresponding to a solution of Laplace's equation, which joins at the minimum a solution ϕ_σ of Eq. (8). The value of σ which belongs to a solution ϕ_σ , having a starting slope $-B_\sigma$, is thus *determined* by numerical integration from $\phi=1$, $x=0$, $\phi'=-B_\sigma$ to the minimum, and by there *assigning* the value $1-\sigma$ to the ordinate $\phi_{\sigma m}$. The value of σ is known to characterize the straight line $1-\sigma=\phi$, which is the solution of Laplace's equation for the region outside of an ion of order σ . This condition expresses the fact that the potential of a positive ion must be

$$v \sim \frac{(Z-z)e}{r} = \frac{Ze}{r} (1-\sigma)$$

for large values of r .

All solutions of Eq. (8) with $-B_1 > -B_\sigma > -\infty$ lie below ϕ_1 and terminate abruptly at $\phi=0$, so that they do *not* represent negative ion distributions. Negative ions, as a matter of fact, will not find a place in any theory which assumes radial symmetry.

Since $x=0$, $\phi=1$ is a winding point with ϕ'' infinite, it is not possible to integrate from there using Taylor's series. Instead the expansions

$$\begin{aligned} \phi = 1 - Bx + \frac{4}{3}x^{3/2} - \frac{2}{5}Bx^{5/2} + \frac{1}{3}x^3 + \frac{3}{70}B^2x^{7/2} - \frac{2}{15}Bx^4 \\ + \frac{4}{63}\left(\frac{2}{3} + \frac{1}{16}B^3\right)x^{9/2} + \dots \end{aligned} \quad (14)$$

and

$$\begin{aligned} \phi' = -B + 2x^{1/2} - Bx^{3/2} + x^2 + \frac{3}{20}B^2x^{5/2} - \frac{8}{15}Bx^3 \\ + \frac{2}{7}\left(\frac{2}{3} + \frac{1}{16}B^3\right)x^{7/2} + \dots \end{aligned} \quad (15)$$

obtained by a method of successive approximations, are used, since they are rapidly convergent near $\phi=1$, $x=0$. Starting with an arbitrary value of B_σ , the integration is carried out to the minimum by an extension of the method given by Whittaker and Robinson⁷ for equations of the first order. The results must be given in a bivariate table, with values of ϕ for each value of x and B_σ or σ . This would be very extensive, were it not for the fact that, for each particular value of x , the values of both ϕ_σ and ϕ'_σ , from one curve to another, depend linearly upon B_σ . By means of the formulae:

$$\phi_\sigma = k(B_\sigma - B_p) + \phi_p \quad (16)$$

$$\phi'_\sigma = k'(B_\sigma - B_p) + \phi'_p \quad (17)$$

⁷ Whittaker and Robinson, "The Calculus of Observations."

and Table I, we may easily find the values of ϕ_σ and ϕ_σ' for each value of σ , at the values of x given in the table. For intermediate values linear interpolation is sufficiently accurate. The constants k and k' , being functions of x , are also tabulated, as well as the values B_p , ϕ_p and ϕ_p' of the reference solutions. The values of $B_{\sigma m}$ and $\phi_{\sigma m}$ are also listed; they are the initial slopes and minimal ordinates, respectively, of the solutions having their minima at the given value of x . Since $\phi_{\sigma m} = 1 - \sigma$, this part of the table is used to find the initial slope B_σ , needed in Eqs. (16) and (17), corresponding to the given order σ of the ion. This may also be done using Fig. 2. In Fig. 3 values of $\phi_{\sigma m}$ are plotted against x_m , and from this, since $\phi_{\sigma m} = 1 - \sigma$, we may find the radius x_m of an ion of order σ .

Values are listed from $x = 0.10$ to $X = 14.88$. For values of $x < 0.10$ the series in Eqs. (14) and (15) may be used.

II. IONIC RADII

Herzfeld⁸ has given a summary of some fourteen different methods of determining ionic radii, most of which are experimental, or semi-experimental. It may be seen from his collection of data, that the radius of any particular ion has a wide range of values, according to the method of determination. This uncertainty is not experimental, but lies in the variation of meaning of the radius with the method. It is consequently quite useless to

expect quantitative agreement of the radii determined by this theory, which themselves have little real meaning, with his values. Never-the-less, they do correspond in order of magnitude, and show the same general variation with atomic number. The class of ions considered by Herzfeld is a restricted class, having values of z equal to $Z-q$, where q is the valence of the element Z . When their radii are plotted against Z , a Lothar Meyer curve is obtained. We have made a similar curve, Fig. 4, of the values found from Fig. 3, but only for elements having positive ions.

III. SUCCESSIVE IONIZATION POTENTIALS

Milne⁹ has applied the Fermi-Thomas theory of the neutral atom to the calculation of the total potential necessary to remove all of the electrons from

⁹ E. A. Milne, Proc. Camb. Phil. Soc. 23, 794 (1927).

a neutral atom. Since our theory also gives a description of positive ions, the natural extension of the work of Milne is the calculation of the *successive* ionization potentials of atoms, or the successive potentials necessary to remove the electrons from an atom one at a time, further "stripping" the atom at each step.

The method of calculation consists in finding the total potential $X = X(\sigma, Z)$, necessary to remove all of the electrons from each kind of a positive ion that an element of atomic number Z may have, including the neutral atom.

Fig. 4.

Successive differences of these quantities give the desired successive ionization potentials.

Milne considered the total electrostatic potential V to consist of two parts, Ze/r due to the nucleus, and $v(r)$ due to the charge cloud. At the nucleus $v(r)$ takes the constant value v_0 , the "back potential" of the charge cloud, and this he showed proportional to the starting slope of ϕ_1 , which is $-B_1$. There is a charge Ze at the nucleus, and at any other point a charge ρv . The total electrostatic potential is then

$$W = \Sigma \frac{1}{2} ev = \frac{1}{2} \int \rho v d\tau + \frac{1}{2} Ze v_0, \quad (18)$$

and the total energy is half of this.

The integral in the first term of Eq. (18) he showed to be proportional to B_1 , which becomes B_e for the ion. His result may be written:

$$X(1, Z) = -13.11 B_1 Z^{7/3} \text{ volts.} \quad (19)$$

He obtained his value of B_1 from Thomas' calculations of ϕ_1 near $x=0$, which, however, are slightly in error. Using our value of $B_1 = -1.588558$, we obtain

$$X(1, Z) = 20.824 Z^{7/3} \text{ volts} \quad (20)$$

which does not agree as well with experiment as Milne's

$$X(1, Z) = 17Z^{7/3} \text{ volts.} \quad (21)$$

This agreement must be regarded as accidental.

For the positive ion of order σ we obtain

$$X(\sigma, Z) = -13.11B_\sigma Z^{7/3} \text{ volts.} \quad (22)$$

If the approximation of Fermi and Razetti is generalized for ions of any order we obtain

$$X_F(\sigma, Z) = -13.11B_1 \frac{7}{13} \left(\frac{6}{7}\sigma + 1 \right) Z^{7/3} \text{ volts,} \quad (23)$$

since z must be used for the evaluation of v in the first term of Eq. (18). In successive differences only the term in Eq. (23) containing σ gives a contribution.

Fig. 5. Successive ionization potentials of oxygen. $Z=8$. Circles represent Hartree's Values.

In Figs. 5 and 6 we have plotted such differences of $X(\sigma, Z)$ for the elements oxygen and iron. The broken curves are the semi-experimental values of Hartree.¹⁰ As with most results of this statistical theory, a smooth curve

¹⁰ D. R. Hartree, Proc. Camb. Phil. Soc. 22, 473 (1924).

running through the jagged experimental one is obtained. Differences of X according to (23) give a curve of successive ionization potentials having a negative slope and going from the upper left hand corner to the lower right hand corner of the diagrams 5 and 6.

Fig. 6. Successive ionization potentials of iron. $Z=26$. Circles represent Hartree's values.

IV. APPLICATION TO THE BEHAVIOR OF OPTICAL TERM VALUES IN THE LIMIT OF VERY HIGH FREQUENCIES

Sommerfeld has shown that x-ray terms may be represented by the semi-empirical term formula

$$-\frac{T}{R} = [Z/n - a(Z, n) - b(n, l)]^2 + \alpha^2 \left[\frac{Z - d(n, l, j)}{n} \right]^4 \left(\frac{n}{j + \frac{1}{2}} - \frac{3}{4} \right) + \dots \quad (24)$$

Laporte¹¹ has shown that this same formula may be used to represent optical terms, though the number $a(Z, n)$, which represents the screening of the outer electrons, is zero for optical terms, and $b(n, l)$ is a function of Z , except for very high ionizations ($\partial < 1$). For low ionizations its dependence upon Z may be expressed as the series

$$b(n, l, Z) = A(n, l) + \frac{B(n, l)}{Z} + \frac{C(n, l)}{Z^2} + \dots \quad (25)$$

so that

$$\lim_{Z \rightarrow \infty} b(n, l, Z) = A(n, l). \quad (26)$$

It is possible to calculate the quantity $A(n, l)$, by means of the present theory, for hydrogenic ion series like Na I, Mg II, Al III, etc. It is also

¹¹ O. Laporte, "Sommerfeld Festschrift," Leipzig, 1928, p. 128.

possible to derive this from the experimental values of the line frequencies for such isoelectronic series. We shall be interested first in the latter problem.

Combining Eqs. (24) and (25) we have:

$$-\frac{T}{R} = \left\{ \frac{Z}{n} - \left[A(n, l) + \frac{B(n, l)}{Z} + \frac{C(n, l)}{Z^2} + \dots \right] \right\}^2 + \alpha^2 \left\{ \frac{Z - d(n, l, j)}{n} \right\}^4 \left(\frac{n}{j + \frac{1}{2}} - \frac{3}{4} \right) + \dots \quad (27)$$

Terms in α^2 and higher powers of α^2 represent the "relativity" correction, and if we subtract them from both sides of Eq. (27), we obtain the "reduced" term values t , thus

$$-\frac{t}{R} = -\frac{T}{R} - \alpha^2 \left\{ \frac{Z - d(n, l, j)}{n} \right\}^4 \left(\frac{n}{j + \frac{1}{2}} - \frac{3}{4} \right) + \dots = \left\{ \frac{Z}{n} - \left[A(n, l) + \frac{B(n, l)}{Z} + \frac{C(n, l)}{Z^2} + \dots \right] \right\}^2. \quad (28)$$

We wish now to be able to calculate $A(n, l)$ from observed values of t . This may be done in at least two ways.

The first is to take the square root of the absolute values of both sides of Eq. (28), obtaining:

$$\left(\frac{t}{R} \right)^{1/2} = \frac{Z}{n} - A(n, l) - \frac{B(n, l)}{Z} - \frac{C(n, l)}{Z^2} + \dots \quad (29)$$

which shows that the Moseley law holds for large values of Z . If we form the difference

$$\left(\frac{t(l_2)}{R} \right)^{1/2} - \left(\frac{t(l_1)}{R} \right)^{1/2} = [A(n, l_1) - A(n, l_2)] + \frac{1}{Z} [B(n, l_1) - B(n, l_2)] \quad (30)$$

and go to the limit for very large Z , we obtain the quantity

$$\lim_{Z \rightarrow \infty} \left\{ \left(\frac{t(l_2)}{R} \right)^{1/2} - \left(\frac{t(l_1)}{R} \right)^{1/2} \right\} = [A(n, l_1) - A(n, l_2)]. \quad (31)$$

This quantity may be directly calculated from the experimental term values of an isoelectronic sequence, it being the asymptotic value that the quantities in Eq. (30) seem to approach for the heavier elements in the sequence. Such quantities have been calculated by Wentzel¹² and Unsöld,¹³ on the basis of a model of the atomic core composed of concentric spherical surface charges. This quantity has the disadvantage that the absolute term values must be known in order to calculate it.

The second quantity which may be used as a medium of comparison of theory and experiment is the asymptotic value of the first differences, for

¹² G. Wentzel, *Ann. d. Physik* **76**, 803 (1925).

¹³ A. Unsöld, *Zeits. f. Physik* **33**, 843 (1925).

neighboring elements in the isoelectronic sequence, of the line frequencies themselves. We may form this quantity from Eq. (28). It is

$$\begin{aligned} & \lim_{Z \rightarrow \infty} \left\{ \frac{\nu(l_2, l_1, Z+1)}{R} - \frac{\nu(l_2, l_1, Z)}{R} \right\} \\ &= \lim_{Z \rightarrow \infty} \left\{ \left[\frac{t(n, l_2, Z+1)}{R} - \frac{t(n, l_1, Z+1)}{R} \right] - \left[\frac{t(n, l_2, Z)}{R} - \frac{t(n, l_1, Z)}{R} \right] \right\} \quad (32) \\ &= \frac{2}{n} [A(n, l_1) - A(n, l_2)], \end{aligned}$$

which is just $2/n$ times the quantity in Eq. (31).

Fig. 7.

Fig. 8.

These two quantities, in Eqs. (31) and (32), have been calculated by means of this theory, and have been compared with the experimental values of Bowen and Millikan¹⁴ for the series Na I, Mg II, etc., and Li I, Be II, etc. in Figs. 7, 8, 9, and 10.

Fig. 9.

Fig. 10.

The use of the present theory to calculate these values involves the Schrödinger perturbation theory, since we are only interested in the energy values for large values of Z (σ nearly 0). We consider the core as a perturbation of an "hydrogenic" atom, writing the perturbation energy as

$$\epsilon = \frac{\int_0^\infty P(r) \psi^2 r^2 dr}{\int_0^\infty \psi^2 r^2 dr} \quad (33)$$

¹⁴ I. S. Bowen and R. A. Millikan, Phys. Rev. **25**, 299 (1925), **27**, 145 (1926).

where ψ is the wave function of the unperturbed hydrogenic atom, and $P(r)$ is the perturbation function of the core. We proceed to construct $P(r)$.

Consider an ion of nuclear charge Z , with z electrons in the core, and one valence electron in addition. The potential energy of the valence electron in the field of the nucleus plus core is

$$-\frac{Ze^2}{r}\phi_\sigma\left(\frac{r}{\mu}\right) \quad (34)$$

where ϕ_σ is the generalized Fermi function for an ion of order σ . The net charge of the ion is $(Z-z-1)$.

The potential energy of the valence electron in the field of the nucleus alone (of charge Ze) is

$$-\frac{Ze^2}{r}. \quad (35)$$

If we add and subtract Eq. (35) to Eq. (34), we still have the potential energy of the valence electron in the field of the nucleus plus core as

$$-\frac{Ze^2}{r} + \frac{Ze^2}{r}\left[1 - \phi_\sigma\left(\frac{r}{\mu}\right)\right] = -\frac{Ze^2}{r} + \Phi. \quad (36)$$

The quantity $\Phi = Ze^2/r[1 - \phi_\sigma]$ may be split into two parts Φ_1 and Φ_2 , such that

$$\Phi = \Phi_1 \text{ for } r \leq r_m$$

$$\Phi = \Phi_2 \text{ for } r \geq r_m,$$

where r_m is the radius of the core. If $r > r_m$, then

$$\phi_\sigma = \phi_{\sigma m} = 1 - \sigma = 1 - z/Z,$$

so that

$$\Phi_2 = \frac{Ze^2}{r}(1 - 1 + z/Z) = \frac{ze^2}{r}. \quad (37)$$

We may rewrite Eq. (36) in the form

$$-\frac{(Z-z)e^2}{r} + P(r) \quad (38)$$

where P is a function defined by

$$\begin{aligned} P &= \Phi_1 - Ze^2/r \text{ for } r < r_m \\ P &= 0 \quad \text{for } r > r_m. \end{aligned} \quad (39)$$

Now, if Z is very large, we may think of the valence electron as being primarily in the field of a point charge $(Z-z)e$, and then being perturbed by

another system, with the perturbation energy $P(r)$. So, without the perturbation we have an hydrogenic atom with nuclear charge $(Z-z)e$ (i.e. the quantity z is the first approximation to the screening number $b(n, l, Z)$).

If $Z \gg z$ (σ nearly 0), we may use the series approximation of ϕ_σ given in Eq. (14), since x_m is also nearly zero. By means of the analytical expressions of Eqs. (14) and (15) we are able to find an analytical expression for B_σ as a function of σ . To do this we notice that at the minimum

$$\phi' = 0 = -B + 2x_m^{1/2} - Bx_m^{3/2} + x_m^2 + \dots \quad (40)$$

Since both B and x_m are small, all terms after the first two are of lower order, so that, approximately,

$$B = 2x_m^{1/2}; \quad x_m^{1/2} = B/2; \quad x_m = B^2/4. \quad (41)$$

Then, substituting in Eq. (14), we have

$$\begin{aligned} \phi_m = 1 - \sigma &= 1 - B(B^2/4) + \frac{4}{3}(B/2)^3 - \frac{2}{5}(B/2)^5 + \dots \\ &= 1 - B^3/12 - B^5/80 + \dots \end{aligned} \quad (42)$$

or, to the same approximation as in Eq. (41),

$$B^3/12 = \sigma; \quad B = (12\sigma)^{1/3} \quad (43)$$

which is the required function. If we eliminate B from Eqs. (14) and (43), we obtain ϕ_σ in terms of x and σ explicitly. Thus

$$\phi_\sigma = 1 - (12\sigma)^{1/3}x + \frac{4}{3}x^{3/2} - \frac{2}{5}(12\sigma)^{1/3}x^{5/2} + \dots \quad (44)$$

and therefore

$$\begin{aligned} \Phi_1 &= \frac{Ze^2}{r} \left[(12\sigma)^{1/3}x - \frac{4}{3}x^{3/2} + \frac{2}{5}(12\sigma)^{1/3}x^{5/2} + \dots \right] \\ &= Ze^2 \left[\frac{(12\sigma)^{1/3}}{\mu} - \frac{4}{3} \frac{r^{1/2}}{\mu^{3/2}} + \frac{2}{5}(12\sigma)^{1/3} \frac{r^{3/2}}{\mu^{5/2}} + \dots \right]. \end{aligned} \quad (45)$$

Finally, we may write our perturbation function as

$$P(r) = Ze^2 \left[\frac{(12\sigma)^{1/3}}{\mu} - \frac{4}{3} \frac{r^{1/2}}{\mu^{3/2}} \right] - \frac{ze^2}{r}; \quad r \leq r_m \quad (46.0)$$

$$P(r) = 0; \quad r \geq r_m. \quad (46.1)$$

If we introduce the dimensionless variable

$$\rho = \frac{r}{r_0}; \quad r_0 = \frac{r(Z-z)}{na_0}, \quad (47)$$

where Ze = the real nuclear charge

$(Z-z)e$ = the nuclear charge of our hypothetical hydrogenic atom

a_0 = the normal radius of the hydrogen atom

n = the principal quantum number,

we have the perturbation function

$$Q(\rho) = P(r) = a + b\rho^{1/2} + c/\rho, \quad (48)$$

with

$$a = \frac{Ze^2(12\sigma)^{1/3}}{\mu} = \left(\frac{Ze^2}{a_0}\right) \frac{8Z^{1/3}}{3^{1/3}\pi^{2/3}} \quad (49.0)$$

$$b = -\frac{4Ze^2}{3\mu^{3/2}} \left(\frac{a_0 n}{2(Z-z)}\right)^{1/2} = -\left(\frac{Ze^2}{a_0}\right) \frac{32n^{1/2}}{9\pi(1-\sigma)^{1/2}} \quad (49.1)$$

$$c = -\frac{2ze^2(Z-z)}{a_0 n} = -2\left(\frac{Ze^2}{a_0}\right) \left(\frac{1-\sigma}{n}\right) \quad (49.2)$$

$$\rho_m = 2\frac{r_m}{r_0} = \frac{2r_m(Z-z)}{na_0} = (1-\sigma) \frac{\pi^{2/3} 3^{4/3} z^{2/3}}{4n} \quad (49.3)$$

and ϵ takes the form

$$\epsilon = \frac{\int_0^{\rho_m} Q(\rho) \psi^2(\rho) \rho^2 d\rho}{\int_0^\infty \psi^2(\rho) \rho^2 d\rho} \quad (50.0)$$

since $Q(\rho) = 0$ for $\rho \geq \rho_m$.

The limiting forms of Eqs. (49) for $\sigma = 0$ are

$$b]_{\sigma=0} = -\left(\frac{Ze^2}{a_0}\right) \frac{32n^{1/2}}{9\pi} \quad (50.1)$$

$$c]_{\sigma=0} = -\frac{2}{n} \left(\frac{Ze^2}{a_0}\right) \quad (50.2)$$

$$\rho_m]_{\sigma=0} = \frac{\pi^{2/3} 3^{4/3} z^{2/3}}{4n}. \quad (50.3)$$

We have passed to the limit several times during the process in order to simplify the calculations. The asymptotic form of the perturbation energy is

$$\epsilon_\infty = -L(n, l, z) \frac{Ze^2}{a_0} \quad (51)$$

If we were to extend the calculation for ϵ near the limit, we would find¹⁵

$$\epsilon = [-LZ + M + N/Z + \dots] \frac{e^2}{a_0}. \quad (52)$$

The energy of the unperturbed hydrogenic ion, of nuclear charge $(Z-z)e$, is

$$E = -\frac{e^2(Z-z)^2}{2a_0n} = -\frac{e^2}{2a_0n}(Z^2 - 2zZ + z^2) \quad (53)$$

and therefore the sum

$$E_p = E + \epsilon = -\frac{e^2}{2a_0n}[Z^2 - 2(Z - n^2L)Z + (z^2 - M) - N/Z + \dots] \quad (54)$$

is the energy of the perturbed ion. From this the reduced term value is seen to be

$$-\frac{t}{R} = \frac{1}{n^2}[Z^2 - 2(z - n^2L)Z + (z^2 - M) - N/Z + \dots] \quad (55)$$

In order to compare this with Eq. (28) we must place the square root of the right hand side under an indicated square. Thus

$$-\frac{t}{R} = \left\{ \frac{Z}{n} - \frac{1}{n}(z - n^2L) - \frac{M - 2zn^2L - n^4L^2}{2Zn} + \dots \right\}^2. \quad (56)$$

Comparing Eqs. (56) and (28) we may make the following identifications:

$$A(n, l) = \frac{1}{n}(z - n^2L) \quad (57.0)$$

$$B(n, l) = \frac{M - 2zn^2L - n^4L^2}{2n}, \text{ etc.} \quad (57.1)$$

From Eqs. (57.0) and (51) we may calculate quantities such as those of Eqs. (30) and (31).

The quantities of Eq. (30), which Wentzel introduced, must be calculated from "reduced" absolute term values. They are practically insensitive

¹⁵ Since the perturbation function has the form of Eq. (48), the perturbation integrals reduce to sums of integrals of the type

$$I(\mu, \nu) = \int_0^\nu x^{\mu-1} e^{-x} dx$$

which are known as "incomplete Γ -functions." They are special cases of the "confluent hypergeometric functions." Tables of these functions have been prepared by K. Pearson ("The Incomplete Γ -function"), but interpolation is very laborious. However, since we encounter only whole or half integral values of μ , it is much simpler to reduce the integrals to polynomials (integral values), or to polynomials plus Gauss error functions, by partial integration.

to relativity corrections, but the absolute term values are only known by somewhat approximate calculations from line frequencies. The unreduced values of Bowen and Millikan are plotted in Figs. 9 and 10.

The quantities calculated according to Eq. (31), though found directly from line frequencies, are very sensitive to relativity corrections, which are difficult to estimate accurately for s terms. Instead, in Figs. 7 and 8, the actual "unreduced" values are plotted for each of the doublet lines, to give an idea of the error involved in not reducing them. The lines on the right hand margin indicate the theoretical asymptotes.

In conclusion I wish to express my appreciation to Professor H. M. Randall, Director of the Physics department, for courtesies shown me during my graduate study at the University of Michigan. I am indebted to Professor O. Laporte for suggesting this problem to me, and for his constant advice. I also wish to thank Professors D. M. Dennison and E. A. Milne for valuable advice and criticism.

FINE STRUCTURE IN THE X-RAY ABSORPTION SPECTRA
OF THE *K* SERIES OF THE ELEMENTS CALCIUM
TO GALLIUM

BY BEN KIEVIT AND GEORGE A. LINDSAY

UNIVERSITY OF MICHIGAN

(Received July 10, 1930)

ABSTRACT

The *K* x-ray absorption spectra of the free elements Ca, Cr, Mn, Co, Ni, Cu and Zn have been photographed and for each of these elements an extended fine structure has been obtained. The fine structure, consisting of six or seven secondary edges, extends over an energy range of more than 200 volts. In every instance the element was used as the absorbing screen except Mn where it was present in the alloy manganin. No detectable difference was found in the absorption spectrum of copper between that obtained with a brass screen and that with the element alone. An attempt was made to show more definitely the relation of the $K\beta_2$ emission line to the principal *K* absorption limit for Fe, Co, Ni and Cu. Indications are that the main edge is produced by the ejection of a *K* electron to an optical level rather than to infinity. It is shown that the Kossel theory alone is quite inadequate to explain all the secondary edges. On the basis of multiple ionization the probable electron transitions have been determined and tabulated to account for the observed separations of the various secondary edges from the principal *K* edge. The methods employed herein to account for probable electron transitions, when applied to the transitions proposed by Ray, in his treatment of the fine structure in *K* and Ca, give very different energy values from those which he has computed.

INTRODUCTION

THE more or less complicated appearance of absorption spectra which is often found on the short wave-length side of the edge is known as absorption fine-structure. Stenstrom,¹ Fricke,² Hertz³ and Lindh⁴ were among those who made the earlier investigations. The latter made an extensive study of the *K* absorption spectra of the elements P(15) to Fe(26) and found as many as three white lines on the plates i.e., in addition to the ordinary absorption discontinuity there appeared lighter and darker regions on the short wave-length side. Coster and van der Tuuk⁵ found a very limited fine structure associated with the *K* edge of argon. An extended fine structure of the edge was found by Lindsay and Van Dyke⁶ in the *K* absorption of calcium, where the element was present in the crystals used as reflectors and served also in the capacity of absorbing material. Nuttall's⁷ investiga-

tion of the *K* edges of potassium and chlorine in compounds showed as many as five secondary edges. Voorhees and one of the authors⁸ have shown that the multiple structure for iron, both as a metal and in compounds, extends over a range considerably greater than that of any fine structure previously reported. They found that the outstanding features for the element alone were in the structure which was apparent in the main edge itself, the absence of the intense white-line absorption, the increase in extent or range of the secondary edges, and verified the fact that the free element has the principal absorption edge of longest wave-length⁹ which should therefore be more characteristic of the substance.

Since metallic iron afforded such an excellent fine-structure it was felt that other neighboring elements in the free state might also under suitable conditions, give an extended structure of the *K* absorption edge. Besides it was hoped that with information regarding the secondary edges of a considerable number of adjacent elements, it might be possible to arrive more readily at a satisfactory explanation for the observed phenomena. It was with such aims in view that the present work was undertaken. The general method employed was that of placing films of the absorbing metal in the path of the x-ray beam and obtaining photographic records of the absorption spectrum by reflection of the radiation from a sylvite or a calcite crystal.

APPARATUS AND EXPERIMENTAL PROCEDURE

A Siegbahn precision vacuum spectrograph was used for obtaining photographs of the absorption edges. For absorption spectra of all the elements investigated a natural potassium chloride crystal served as the reflector. The dispersion with this crystal varied from about 15 X.U. per mm for Ca to about 17 X.U. per mm in the case of zinc. Since the secondary edges become more crowded together with increasing atomic number it was necessary to increase the dispersion for Cu and Zn in order to obtain plates showing the fine structure which could be measured with a fair degree of accuracy. Accordingly, a calcite crystal was ground parallel to the (111) planes and mounted in the usual manner. This provided a dispersion of about 7 X.U. per mm.

Proper screens are one of the most essential requirements necessary to insure success in obtaining fine structure in the absorption edges. One must have uniformity as well as optimum thickness and both of these are troublesome factors in many cases. An excellent principal edge can be produced with screens which are either too thick or too thin to show the secondary edges. The surest method of determining the proper thickness is by trial.

Using such a trial method it was found that a nickel film about 0.007 mm thick gave excellent fine structure. This nickel had been prepared electrolytically and annealed in hydrogen. The copper, brass and zinc screens were prepared simply by carefully rolling out the metals to suitable thicknesses. It may be pointed out here that the results obtained for copper in

⁹ Kath. Chamberlain, *Nature* **114**, 500 (1924), *Phys. Rev.* **26**, 525 (1925).

brass showed no measurable deviations from that obtained when copper screens were used.

Considering the results obtained with brass screens for copper fine structure it was thought permissible to use an alloy of manganese as an absorber. Manganin, a copper-manganese alloy containing 15% manganese, was used since it could be easily rolled to the proper thickness and also because the manganese content is high in this alloy.

The preparation of cobalt screens presented no difficulties. The metal was deposited electrolytically on chromium plated electrodes from which it was then easily removed. The chromium screens required a different procedure. Due to its extreme hardness and brittleness rolling was out of the question. A layer of Cr about 0.003 mm thick was plated on a thin steel electrode. Then a thin coating of paraffin was applied over the Cr to strengthen the film, this added support being necessary during the following chemical process. HCl was used to etch away the iron from a small area leaving the Cr film which was supported by the remainder of the steel.

Calcium screens required extra precautions due to the rapid oxidation. Pure Ca was rolled out to the desired thickness and immediately given a thin coating of paraffin. In this manner Ca films could be used for a hundred or more hours.

Although no very definite results were obtained for gallium (31) and selenium (34), as far as fine structure is concerned, the preparation of these screens is described. Ga melts at 30.1°C . Like Hg in the liquid state its surface tension is great. Fortunately one is able to spread it out into a thin layer when applied on aluminum. If the Al is used in the form of thin foil there will be only a very slight amount of absorption due to this element since the wave-length of the *K* edge of Ga is below 1.2Å. Selenium screens were made by heating the element somewhat above its melting point and then when temperature conditions were just right it was possible to spread out the substance on thin pieces of paper. Here again the amount of absorption by the supporting material was negligible.

Measurements on all plates were made on a comparator having a least count of 0.005 mm. In making settings on the various edges the cross-hair of the instrument was brought across the blackening to such a position that it was possible just to see no falling off in the intensity on the long wave-length side of the cross-hair. Settings were also made on any good emission lines, if they were present on the plate, since they served as convenient reference lines to determine the wave-length of the principal edge and also permitted a check on the dispersion for the adjacent regions. The photometric curves incorporated in this paper were made on a Moll microphotometer. Duplicate runs over different portions of the plate gave curves which were essentially the same.

To aid in the interpretation of the fine structure data additional plates were made to show more definitely the location of the KB_2 line of an element with respect to the principal *K* absorption limit of the same substance. Copper, nickel, iron and cobalt were studied. The method employed was

to photograph on a plate the main K edge and any suitable reference line so that the distance between these two could be measured on the comparator. On another plate the emission spectrum of the element was obtained in which the $K\beta_2$ line was sufficiently prominent to be measured. The same reference line was photographed with the $K\beta_2$ line and therefore the distance between the lines could be determined. In each case of absorption the screens were of the free element, no attempt being made to obtain fine structure. For copper absorption the continuous spectrum came from a molybdenum target while in the other three cases a copper anode was employed. This procedure prevented the appearance of the $K\beta_2$ line in the absorption spectrum and therefore aided in making more reliable settings on the main edge. For the emission spectra targets of these various metals were used. At least two plates of each type for each element were obtained and measured.

In every case the value used in the computation of the wave-length of edge or line was the mean value of ten settings on the comparator. The general method used was that of reference measurements. Since the wave-length of the principal absorption edge depends upon the chemical combination of the absorber it was desirable to determine the wave-length of the absorption limits for each of the free elements studied. Having determined the wave-lengths of the main K edge for each element the wave-lengths of the secondary edges were computed by multiplying each linear separation, from the principal edge to the secondary edge, by the proper dispersion factor and subtracting each product from the known absorption limit. The reciprocal of the wave-length gives the frequency ν in cm^{-1} and division by the Rydberg constant 109737 gives ν/R for each edge. The separation $\Delta\nu/R$ of any secondary edge from the main edge may then be expressed in equivalent volts by multiplying the by the factor 13.56.

DATA AND RESULTS

I. Wave-Length determinations of principal K absorption limits.

In Table I have been recorded the mean values, expressed to the nearest 0.1 X.U., of the principal K absorption limits. The value of iron is included, this result having been taken from the work of Voorhees and one of the authors.⁸

II. Absorption fine structure.

The general appearance of the plates showing absorption spectra in which the principal edges are accompanied by several secondary edges

may be seen in Fig. 1. The micro-photograms are reproduced in Fig. 2. The discontinuity designated by "K" marks the location of the main edge

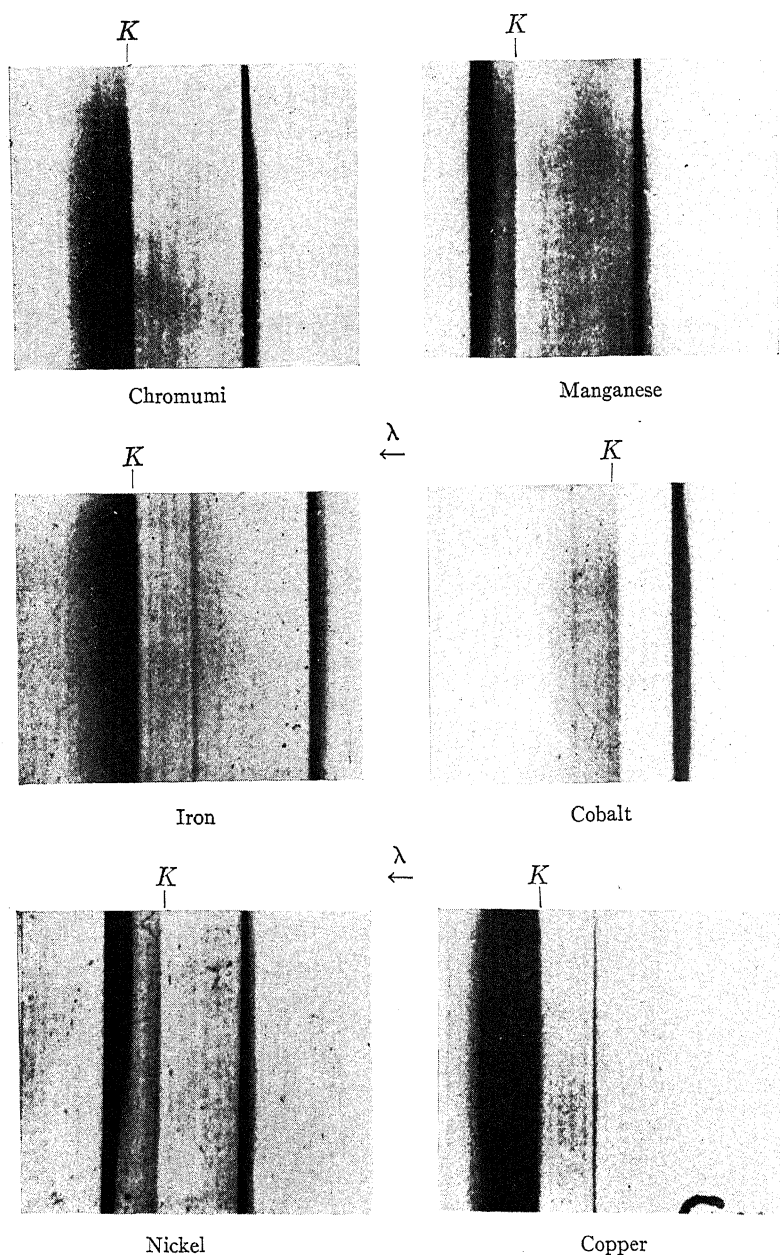

Fig. 1. Fine structure in the absorption spectra of the K series of several elements.

and it is in the lighter region to the short wave-length side of this edge that one observes the fine structure, whose general appearance is that of a series

of alternately light and dark regions. The "white lines" are not of the same width, nor of the same intensity, neither are they equally spaced on the plate but appear farther and farther apart as one proceeds to shorter wave-lengths. In the discussion below an attempt is made to trace the most

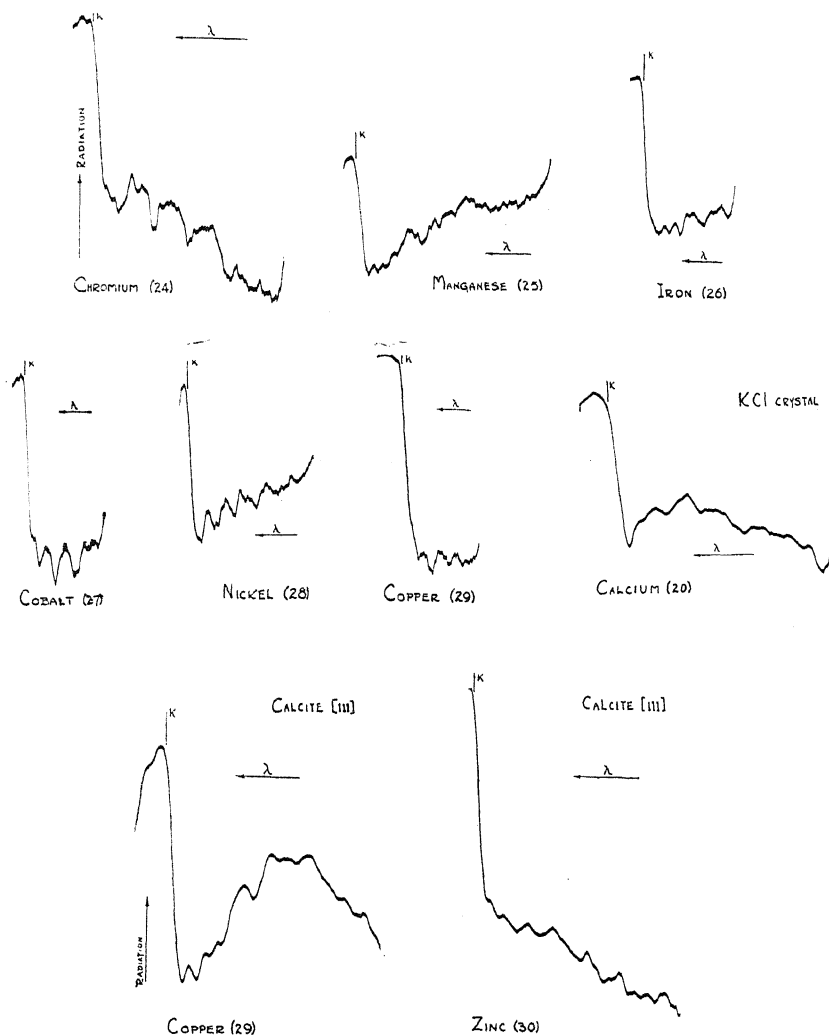

Fig. 2. Photometric records of *K* x-ray absorption spectra.

intense white line, or better, the adjacent secondary edge, through the various elements.

The results obtained from data on each element for which fine structure was observed and measured have been collected in Table II. In this table are given the mean values of the wave-lengths of the secondary edges, expressed to 0.1 X.U. together with the separations of these edges from the

principal edge. The separations are tabulated in ν/R units as well as in equivalent volts. The values for iron were taken from the results of Lindsay and Voorhees⁸ and were incorporated in order to have a complete sequence from Cr to Zn.

III. Relation between the $K\beta_2$ line and the principal K edge for the elements Fe, Co, Ni and Cu.

In the discussion of possible electron transitions corresponding to secondary edges it is evidently necessary to know as much as possible of the transition related to the principal edge. It has been rather assumed that the K electron goes to infinity. Now the $K\beta_2$ line represents a transition from the $N_{II,III}$ level to the K level, and if the K electron in absorption goes to infinity we should have for the elements here considered a difference between the K edge and the $K\beta_2$ line about equal to the first ionization potential.

Fig. 3. K absorption and emission spectrum of copper.

Measurements from a number of plates of the relative positions of the K edge and the $K\beta_2$ line with respect to a chosen reference line show a separation smaller than that of the ionizing potential. The difference also varies with different elements. In fact, for nickel, what we have been accustomed to take as the position of the K edge is slightly longer in wave-length than the $K\beta_2$ line, while for Cu the two are sensibly the same. Fig. 3 shows the K absorption spectrum and the $K\beta_1$ and $K\beta_2$ emission lines for Cu photographed on the same plate. The reference lines is $PtL\alpha_1$.

THEORETICAL ASPECTS OF THE PROBLEM

Several hypotheses have been set forth to account for the observed structure of x-ray absorption edges. Since in this investigation free elements were used as absorbers there was no possibility of observing the white line absorption on the long wave-length side of the principal edge, similar to that found by Coster¹⁰ and by Lindh,¹¹ resulting from reduction of the com-

¹⁰ D. Coster, *Zeits. f. Physik* **25**, 83 (1924).

¹¹ A. E. Lindh, *Zeits. f. Physik* **31**, 210 (1925).

pounds in the screen by the x-ray beam thus producing some of the free element. It has been demonstrated that the free element has its principal absorption limit at a longer wave-length than any of the ionized forms.

According to Kossel's¹² viewpoint, published in 1920, the principal K absorption limit corresponds to the absorption of a quantum of energy sufficient to eject a K electron to the first permissible, unoccupied orbit. For the elements studied in this investigation this would mean a transition from the K level to the N_{II} level, or what is the same, from a $1s$ to a $4p$ state. That many atoms are excited to this state by the absorption of energy, is evidenced by the fact that the $K\beta_2$ line is emitted with considerable intensity by these elements. Thus one may conclude, as did Kossel, that the probability of a K electron stopping in the first unoccupied orbit is large. However, it is very likely that in many atoms the K electron would be ejected to the $5p$ or $6p$ level if the atom absorbed a quantum sufficient for such a jump. One would therefore expect absorption limits corresponding to these various transitions. The limiting position for these secondary edges would be that which corresponds to absorption of energy sufficient to remove a K electron completely from an atom. The energy required would be in excess of that for the principal edge by an amount corresponding approximately to the first ionization potential of an atom of atomic number one greater. The first ionization potentials for the elements under consideration are 6 to 9 volts. Edges within this small range are hardly to be detected although results indicate that the separation of the first secondary edge corresponds to the limiting value, that is, to the energy of ionization. Coster and Van der Tuuk in their study of the K edge of argon found a secondary edge at 1.7 volts from the main edge. They attributed this to the absorption of energy sufficient to eject a K electron to one of the optical levels of the atom.

There is rather convincing evidence that the main edge results from absorption of energy which will remove a K electron to an outer orbit rather than from that which would completely remove the K electron from the atom. As stated under Part III, the principal edge, at least for iron, cobalt, nickel and copper, has a separation from the $K\beta_2$ line which is never more than about half the ionizing potential. The $K\beta_2$ line is ascribed to the transition of an electron from the N_{II} level to the K level. To exactly what orbit the K electron goes in the absorption process is difficult to say, although the results would indicate an excitation to a higher optical level in the cases of cobalt, iron and copper than in nickel. Allowance for this condition was made in the determination to account for the secondary edges.

The extent of absorption fine structure such as that observed by Lindsay and VanDyke for calcium in calcium compounds, by Nuttall for potassium and for chlorine in compounds of those elements, by Lindsay and Voorhees for iron (free and in combinations), by Coster¹³ for copper and that by the authors has all been such that Kossel's theory, which he himself

¹² W. Kossel, *Zeits. f. Physik* 1, 119 (1920).

¹³ D. Coster, *Nature* 124, 652 (1929).

pointed out would explain only a small range of fine structure, would alone be quite inadequate to account for it. Secondary edges occur whose separations from the main edge are much greater than that which one could ascribe to an amount of energy of the order of the first ionization potentials. Thus one is led immediately to the supposition that a multiple ionization may result from the absorption of a single quantum of energy. It was this idea of multiple ionization that Wentzel¹⁴ proposed to account for the so-called "spark lines" or non-diagram lines which were found in x-ray emission spectra.

If Wentzel's hypothesis is a valid one to account for the emission of the "spark" lines then the atoms must absorb energy sufficient to excite them to the states which would give rise to such lines and one ought to be able to obtain absorption edges for the corresponding states. Lindsay and Voorhees, in their work on the K absorption in iron and iron compounds sought to locate an edge which would result when the incident quantum of energy ejected an L electron with a K electron. This edge would have a separation of about 750 volts from the principal edge. The indications of such an edge were too feeble to furnish any conclusive evidence for this double ionization. Likewise, no one has reported absorption edges to confirm a double ionization of the K state. However, this does not lead to the conclusion that simultaneous multiple ionization is improbable. Ionizations involving K and M or N electrons may occur and edges corresponding to these have been found by several investigators.

To calculate the energy difference in states represented by the separation of any secondary edge from the main edge one must know, or determine, or possibly assume, the electron transition which resulted from absorption of energy to produce the main edge. It was by means of measurements on the K edge and $K\beta_2$ line for several elements that one could say with some degree of assurance to which orbit the K electron went in the case of the main edge.

Consider first the zinc absorption spectrum. Zinc, atomic number 30, has the normal configuration of electrons $3d^{10} 4s^2$, and all the inner orbits are filled. To excite the atom to the K state means that a K electron must be ejected at least to an N_{II} level, i.e., to a $4p$ orbit. This will be designated by ($K \rightarrow N_{II}$). The ejected electron cannot stop in an inner orbit since there are no vacant ones in the neutral zinc atom. If this be the case then the wave-length for the main edge would correspond exactly to the wave-length of the $K\beta_2$ line. Although this was not verified for zinc in a manner similar to that for iron, nickel, cobalt and copper, there are other reasons to believe that one should attribute the main K edge to the transition $K \rightarrow N_{II}$ as recorded in Table III under zinc. In the first place it seems reasonable to assume that when one K electron is missing, then to an outer electron the nucleus and remaining K shell together, or the core of the atom, is very much like the central portion of the element with atomic number one

¹⁴ G. Wentzel, Ann. d. Physik 66, 437 (1921)

greater. Thus the nucleus and *K* shell of neutral zinc taken as a unit acts like a charge of 30-2 or 28 to an outer electron. This assumes that the *K* electrons have a complete screening effect. But with one *K* electron gone the effective charge would be 29. This is just the value of the charge of the

core of neutral gallium. The electron configuration for gallium is $3d^{10}4s^24p$. Hence the K electron of zinc in being ejected by the absorption of energy sufficient to excite the K state would probably stop in the $4p$ orbit so as to give an outer configuration like gallium, and there would now be 29 electrons outside the K shell just as there are in neutral gallium.

Further evidence that this assumption is valid comes from the results expressed in Table III for the energy separations of the secondary edges in the zinc absorption spectrum. By taking the K electron to an N_{II} level for the main edge remarkably good agreement has been obtained between calculated and observed values for the energy separations of secondary edges from the K edge. The method employed in calculating these energy separations follows.

Column one in Table III lists the edges in order of decreasing wave-length beginning with the main edge (which has the longest wave-length) marked

"K". In the second column appear the probable electron transitions which involve absorptions of energy of sufficient amounts to account for the observed edges. Calculated and observed values (expressed in the customary ν/R units) of the energy differences which correspond to the separations of the main and secondary edges are given in the last two columns.

Confining attention to the tabulation on zinc, one notes that the K edge has been recorded as resulting from the transition $K \rightarrow N_{II}$ as mentioned above. The first secondary edge, might arise from the transitions:

$$(K \rightarrow \infty) + (N_I \rightarrow N_{II})$$

which may also be written as: $(K \rightarrow N_{II}) + (N_I \rightarrow \infty)$ although the former is easier to compute. The additional energy involved here, above that for $(K \rightarrow N_{II})$, may be determined since it amounts to:

$$(N_{II} \rightarrow \infty) + (N_I \rightarrow N_{II}).$$

Keeping in mind that the configuration after $(K \rightarrow N_{II})$ is $3d^{10}4s^24p$, it is evident that the term $(N_{II} \rightarrow \infty)$ requires energy measured by the first ionization potential for gallium which is 5.97 volts or 0.44 in ν/R units. One must then add to this the energy to excite a gallium ion from a $4s^2$ state to a $4s4p$ state. From Ga II, as given by Sawyer and Lang¹⁵, the separation of these states is about 0.67 in ν/R . Hence the total separation of the first secondary edge from the K edge is $0.44 + 0.67 = 1.11$ whereas the observed value is 1.15.

For edge #2 we have written:

$$(K \rightarrow \infty) + (N_I \rightarrow \infty)$$

and since we are interested in the separation from the K edge we may write:

$$(N_{II} \rightarrow \infty) + (N_I \rightarrow \infty).$$

The first term as before is the energy to ionize the gallium atom once leaving the configuration $4s^2$, and the second term is the energy to remove the second ion after the first one is gone or, in other words, the second ionization potential which one obtains from the Ga II spectrum. Its value is 20.45 volts or 1.51 in ν/R . Thus the energy difference is computed to be: $0.44 + 1.51 = 1.95$. This corresponds favorably with the observed value of 2.0.

The next edge involves changes in the atom whereby two electrons, a K electron and an M_{IV} electron, are ejected from the atom. The transitions are given by:

$$(K \rightarrow \infty) + (M_{IV} \rightarrow \infty)$$

Similar to the preceding case the first term requires 0.44 in ν/R units to ionize the atom once. With the values of the energy levels as given in the thesis of F.P. Mulder,¹⁶ the energy to remove an M_{IV} electron to an N_{II} level is found to be 1.6. But to remove the M_{IV} electron completely from

¹⁵ R. A. Sawyer and R. J. Lang, Phys. Rev. 34, 712 (1929).

¹⁶ F. P. Mulder, Diss. Groningen, 1927.

the atom will take more than that amount. In the computation for the first secondary edge it was seen that $(N_I \rightarrow N_{II})$ required 0.67 providing the K electron was ejected to infinity, while in #2 the energy was the second ionization potential if $(N_I \rightarrow \infty)$. Hence to take the M_{IV} electron out completely would require $1.51 - 0.67$ or 0.84 in addition to that necessary to eject it from an M_{IV} level to the N_{II} level. This gives as the total energy of separation of the third edge from the main edge:

$$0.44 + (1.6 + 0.84) = 2.88.$$

The observed value for this edge is also equal to 2.88.

Edge #4 may be accounted for by the transitions:

$$(K \rightarrow N_{II}) + (M_{IV} \rightarrow \infty) + (M_{IV} \rightarrow N_{II})$$

and for the separation value we need consider just the last two terms. With the K electron stopping in the N_{II} orbit the atom is much like neutral gallium. We need therefore 1.6 in ν/R to take an M_{IV} electron to the N_{II} orbit but this time only 0.44 more to remove it entirely from the atom since this amounts to the first ionization. Hence the term $(M_{IV} \rightarrow \infty)$ requires $1.6 + 0.44 = 2.04$. The next step necessitates the excitation of a second M_{IV} electron to the N_{II} level. Since one electron has already been taken from this group it should require more than 1.6 for the second M_{IV} electron. In order to estimate what increase ought to be made one needs to consider the value of the screening constant for the $M_{IV,v}$ levels, which Sommerfeld¹⁷ gives as 13.0. This means that the average screening effect for each electron is not more than about one half so that it seems reasonable to assume the value of the M_{IV} level to be increased by approximately one third the amount that the germanium M_{IV} level exceeds the gallium M_{IV} level. Thus the term $(M_{IV} \rightarrow N_{II})$ requires 1.9 and the total amount of energy that corresponds to the separation of edge #4 from the K edge is:

$$1.6 + 0.44 + 1.9 = 3.94.$$

Experimentally the separation was found to be 3.95.

The fifth secondary edge is associated with the following changes in electron configuration:

$$(K \rightarrow \infty) + (N_I \rightarrow \infty) + (M_{IV} \rightarrow \infty)$$

which may be written:

$$(K \rightarrow \infty) + (N_I \rightarrow \infty) + (N_I \rightarrow \infty) + (M_{IV} \rightarrow N_I)$$

since in both the resulting configuration is the same, and the latter form lends itself more readily to computation. Considering again only the energy corresponding to the separation of the secondary edge and the K edge we may write:

$$(N_{II} \rightarrow \infty) + (N_I \rightarrow \infty) + (N_I \rightarrow \infty) + (M_{IV} \rightarrow N_I)$$

¹⁷ A. Sommerfeld, "Atomic Structure and Spectral Lines," Methuen, London.

and recalling that the configuration after ($K \rightarrow N_{II}$) is $3d^{10}4s^2 4p$ we see that the first, second and third terms require energy equal to the first, second and third ionization potentials of gallium respectively. The last term amounts to the excitation of a Ga^{+++} ion from a $3d^{10}$ state to a $3d^9 4s$ state. From the Ga IV spectrum as reported by Mack, LaPorte and Lang,¹⁸ the separation of the terms $3d^{10}$ and $3d^9 4s$ is approximately 1.3. The four terms above give then:

$$0.44 + 1.51 + 2.5 + 1.3 = 5.75$$

compared with 5.71 which is the observed value for the separation in energy of the fifth secondary edge from the K edge.

In quite an analogous manner one can account for the other observed secondary edges. For each case one must choose those transitions such that the energy involved will correspond as nearly as possible to the observed values. This has been done for six more edges in zinc as well as for those found for the other elements studied. In most cases the agreement is good.

The question naturally arises as to the uniqueness of the transitions involved. Are there other possible combinations of transitions that will serve equally well to account for any given edge? In most instances the answer would probably be in the negative. One exception has been recorded in Table III for edge #1 in nickel. For the first few edges in each spectrum one must restrict the choice of electron transitions to those involving only the outer or valence electrons, since levels inside $M_{IV,V}$ are already too deep. In contrast with this one has difficulty (especially with the lighter elements studied) in finding transitions which involve enough energy to account for the shortest wave-length secondary edges. As mentioned above, changes calling for transitions from the L levels do not aid in this situation since one change such as ($L \rightarrow M$) would involve too much energy to account for any observed secondary edge.

The predominating factors which governed the choice of transitions to account for a given separation (other than that the total energy be correct) were:

- (1) the electron configuration corresponding to the K edge
- (2) minimum number of electron transitions.

The first of these had been discussed at length under the calculations of the various secondary edges. Some verification of the second is shown by the fact that the most prominent secondary edges seem to be associated with those changes in which the K electron and only one other (usually an M_I or an M_{II}) electron are excited. Thus two electron jumps seem more probable than those involving three or more, which is to be expected.

In connection with this characteristic feature concerning the excitation of M electrons with K electron it has been mentioned above that Coster has observed a fine structure in copper that is in good agreement with the results herein reported for that element. However, he obtained no secondary

¹⁸ J. E. Mack, Otto Laporte and R. J. Lang, Phys. Rev. 31, 748 (1928).

edges in zinc and attributed this negative result to the fact that in zinc (normal configuration $3d^{10}4s^2$) the $3d$ group of electrons is completely filled, so that it would be much more difficult to break into this configuration than it would be in the case of let us say—iron, nickel or even copper. A glance at Table III will indicate, however, that transitions of M electrons enter into practically every computation for zinc secondary edges.

When one compares the general method of computing the energy separations of the secondary edges from the K edge as outlined and applied in this investigation with the method used by Ray¹⁹ for potassium, calcium and chlorine, it is very evident that there will be wide deviations in the results. One or two specific calculations will be given to confirm this statement.

Ray has used the experimental data of Nuttall⁷ for potassium in various compounds, and also the data of Lindsay and Van Dyke⁶ for calcium in calcium compounds. The normal configuration of potassium is $2p^64s$. The K edge, according to Ray, is associated with the transition ($K \rightarrow \infty$). The first secondary edge is related to the change:

$$(K \rightarrow \infty) + (N_I \rightarrow \infty)$$

so that the separation of this edge from the main edge is due to the term ($N_I \rightarrow \infty$) which Ray gives as the first ionization potential of potassium or 4.1 volts. The observed value for the separation varies from 2.8 to 4.9 volts in different compounds. Several objections to this treatment may be noted.

In the first place, when the K electron is ejected either to an outer orbit or to infinity it seems more reasonable to assume that to an outer electron, such as an N_I electron, the core of the atom should be more like calcium than potassium. If the K electron remained in the outer portion of the atom then the transition ($N_I \rightarrow \infty$) ought to correspond to the first ionization potential of calcium (6.09 volts), instead of to that for potassium (4.3 volts). But with the assumption that the K electron is ejected to infinity one ought therefore to regard ($N_I \rightarrow \infty$) as requiring energy equal to the second ionization potential of calcium which is 11.8 volts rather than 4.1 volts. A further objection arises since the potassium is present as an ion and not as an atom in the free state. In the ionic state there might not even be an N electron which could be ejected. The calculations on subsequent edges for potassium are also open to quite similar objections.

Ray's treatment of the calcium edges seems equally unsatisfactory. The normal configuration is $2p^64s^2$ and for the K edge he has assigned the transition ($K \rightarrow \infty$). For the first edge he gives as the electron jumps:

$$(K \rightarrow \infty) + 2(N_I \rightarrow \infty)$$

so that the latter term involves the energy which corresponds to the separation of this edge from the main edge. This he gives as twice the first ioniza-

¹⁹ B. B. Ray, Zeits. f. Physik 55, 119 (1929).

tion potential for calcium (6.1 volts) or 12.2 volts, as compared with the observed value of 13.3 to 16.0 volts.

Neglecting the fact that the calcium is in a compound, the following interpretation of the transitions:

$$(K \rightarrow \infty) + 2(N_I \rightarrow \infty)$$

seems more preferable:

Since the K electron is completely ejected the atom is now much like ionized scandium (Sc^+). Removing one of the N_I electrons would require energy equal to the second ionization potential of scandium which is 12.8 volts. To remove the second N_I electron ought to take an amount of energy equal to the third ionization potential which is about 25 volts. Thus the total energy separation would be approximately 38 volts instead of 12.2 volts as given by Ray. The value for the next secondary edge in calcium is about 31 volts. Thus the transitions:

$$(K \rightarrow \infty) + 2(N_I \rightarrow \infty)$$

as chosen by Ray, which under our interpretation given above corresponds to an energy separation from the K edge of 38 volts, represent not only a great deal in excess of the 15 volts demanded for the first edge, but even too much to account for the separation of the second secondary edge from the main edge.

FALSE LINES IN X-RAY GRATING SPECTRA

By J. M. CORK

DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received July 5, 1930)

ABSTRACT

Because of the arrangement of slits, x-ray source and diffraction grating generally employed in x-ray spectroscopy, certain false lines may be obtained on the photographic plate in addition to those due to defects in the grating. Spectrograms of such spurious lines having their origin in a non-uniform focal spot or reflection from slit faces, as well as those due to certain grating imperfections are shown. One type of companion line is present at wave-lengths about 13 percent greater than the parent line, whose origin is not explained.

THE existence and explanation of false lines in grating spectra in the optical region has been dealt with by many writers. Meggers and Kiess, Anderson and Runge¹ have treated the lines known as Rowland ghosts and Lyman ghosts in spectra obtained with several particular gratings. Since such false lines or 'ghosts' may occur in any spectral region and be of intensity comparable with that of fainter true lines, they may lead to confusion in interpretation of the spectra. In x-ray spectra, beside false lines of this type there may occur others due to the nature of the source. Fig. 1 shows spectrograms illustrating false lines of four different types. While with sufficient care most of these false lines may be avoided, the possibility of their existence makes them worthy of description.

The arrangement of x-ray source, slits and grating usually employed is shown in Fig. 2. Slit widths are generally less than 0.1 mm and the distance between slits *A* and *B* not less than 15 cm. The minimum width of spectral line to be expected for a given set of conditions may be readily computed by means of the diffraction formula $\lambda = d(\cos\theta - \cos\phi)$ where λ , d , θ and ϕ denote respectively wave-length, grating constant, grazing angle of incidence, and grazing angle of diffraction. For a slit width at *A* of 0.1 mm and distance between slits of 15 cm, assuming the grating very close to the second slit, a variation is obtained in the grazing angle θ at the grating of 2.27 minutes of arc which combined with an assumed width of 0.1 mm at *B* would give a maximum variation of 4.54 minutes of arc. It is perhaps remarkable that this apparently unfavorable slit arrangement when used with a grating having 30,000 lines per inch and an incident angle θ of 20 minutes of arc for the first order molybdenum *L* series lines as shown in *A* Fig. 1 should yield a variation in ϕ of only 40 seconds of arc. This divergence in the diffracted beam would cause an increment in width of line on a photographic plate at a distance of 50 cm of only 0.097 mm. For higher orders the width is cor-

¹ Meggers and Kiess, Anderson and Runge, Jour. Opt. Soc. and Rev. Sci. Ins. 6, 417 (1922).

respondingly reduced so that for the fourth order spectrum under the same conditions the maximum width increment is 0.0531 mm. Now while slits 0.1 mm wide when used with the 30,000 line grating as shown yield lines of satisfactory sharpness, with coarser gratings and larger values of the incident angle θ , much wider lines are produced. Thus for an incident angle of 40 minutes and a grating of 14,400 lines per inch a divergence in ϕ of 2.0 minutes of arc is obtained, giving a width increment of 0.29 mm for the first order L series lines of molybdenum.

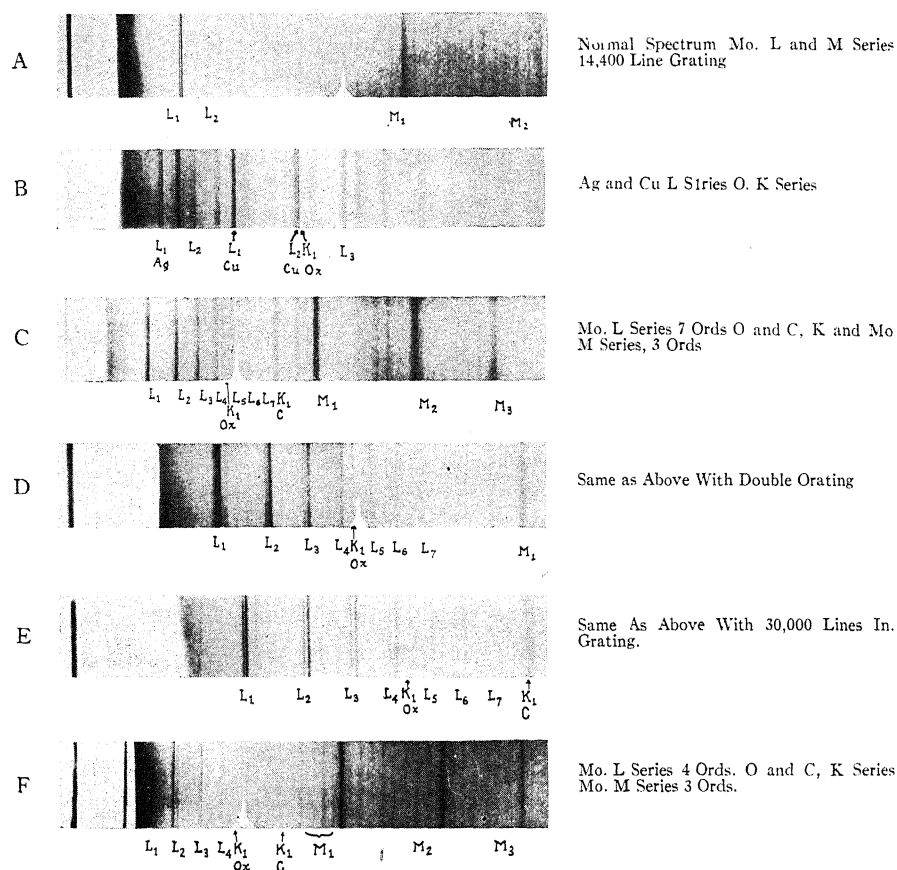

Fig. 1. Spectrogram showing false x-ray lines.

In this case the line very often appears to consist of a group of very fine lines. This fine structure may be due to either of two causes, namely (a) a multi-point focal spot on x-ray target, (b) reflection or scattering of ex-radiation from the faces of slit A. Spectrogram C in Fig. 1 illustrates this multiple structure. The $L\alpha_1$ line on the original photographic plate shows clearly as five fine lines. This is undoubtedly due to the existence of several radiating spots in the main focal spot. These fine spots originating perhaps by surface irregularities become heated to incandescence and are plainly

visible. A multiplicity of this sort might account for the fine structure reported for the $K\alpha$ line of carbon² as it would be in agreement with the statement that the relative intensity of the observed components varied with voltage. The second type of defect may be produced if the main part of the focal spot is not included between limiting lines drawn through slits *A* and *B* as shown in Fig. 2, but lies outside as at *C*. This may result in a line of the usual width with more intense blacking at either border, the type of line depending upon relative position of focal spot and slits as well as shape of slit faces. In spectrogram *D*, Fig. 1 each main line has a blacking of this type on the long wave length side disappearing at high orders. Similarly if the total focal spot is very small and located as at *m* in Fig. 2, then a strong-fine line with a faint companion on each side might be obtained. These defects may be largely reduced by using sharp slit faces arranged as shown in Fig. 2 with a narrow opening.

Another peculiar type of defect in spectra is shown in spectrogram *D*, Fig. 1. In this case each line is doubled and the distance between components

Fig. 2. Arrangement of target, slits and grating in x-ray spectrograph. (Relative slit width enlarged.)

is the same regardless of the distance between grating and photographic plate and varies only slightly with the spectral order. An examination of the grating showed that in the part of the surface being used there were two surface levels due perhaps to some abrupt change in condition during the ruling process, this being a portion of a test grating. Two such parallel gratings when used at grazing incidence would produce doubled lines having a minimum separation of $\sin\phi/\sin\theta$ times the difference in level. A proper selection of grating surface would of course avoid defects of this sort.

Rowland ghosts as observed in optical spectra would be difficult to observe in the x-ray region. They consist of spurious lines close to and on each side of the real line with apparent wave-lengths

$$\lambda_g = \lambda(1 \pm n/Nm)$$

where *n* and *m* denote the order of spurious line and order of real line respectively, and *N* stands for the number of lines ruled for one revolution of the ruling machine screw. These lines are due to the superposition of a coarser period upon the nominal period of the grating caused by imperfections connected with the pitch of the screw in the ruling machine. Such false lines may have intensities less than 1/1000 that of the parent line for gratings

² Bazzoni, Faust and Weatherby, *Nature* **123**, 717 (1929).

ruled on the excellent machines now existant. This low intensity, combined with the minute separation that would be obtained for say a 30,000 line per inch grating in high orders, make ghosts of this type of no moment in x-ray spectroscopy.

False lines of the Lyman type having wave-lengths such as $3/5$, $4/5$, $6/5$, $7/5$ etc. the wave-length of a real line but with intensities less than $1/1000$ that of the parent line might be observed in the x-ray region. These lines have been explained by Runge as due to the superposition of two periods on the grating, one large and one small but neither necessarily a simple multiple of the fundamental period, caused by some mechanical irregularity in the ruling machine. In spectrogram *F*, Fig. 1 the principal Mo *M* line whose wave-length is 64.52 Å is shown over-exposed in three orders. Situated almost symmetrically with each of these are two pairs of fainter lines. The inner pair is separated from the parent line by fractional wave-length differences of 0.067 less and 0.073 more than the central line. The wave-length (of that one) of the outer pair on the short wave-length side is 55.17 Å which agrees with a wave-length value already attributed to a molybdenum *M* line.³ The component on the long wave-length side may be a satellite of the type to be described in the following paragraph. Although the arrangement of these lines looks suspiciously like a parent line with satellites on either side, there is no definite assurance so far, that they are not all real lines.

It will be observed in Fig. 1 in every spectrogram that on the long wave length side of every strong line there appears a companion line of perhaps $1/10$ the intensity whose wave-length is approximately 1.133 times that of the strong line. The principal lines in most of these spectra are the Mo *L*, α_1 and β_1 lines. Wave-lengths greater than the α_1 and β_1 , by the factor 1.133 would come very close to the fainter Mo *L* series, 1 and η lines. However, the relative intensity of these lines is not similar to that found for the 1 and η lines in crystal spectrometry. Further, similar lines are found on the long wave-length side of the copper $L\alpha_1$ and oxygen $K\alpha$ lines in the same relative position as shown in spectrogram 3, Fig. 1. Accompanying lines of this sort were obtained in the same relative position, both with gratings ruled 14,400 lines per inch on the University of Michigan ruling machine and those with 30,000 lines per inch from Johns Hopkins University. At present a satisfactory explanation of these lines is not available.

THE ARC SPECTRUM OF PALLADIUM

BY A. G. SHENSTONE,

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received June 30, 1930)

ABSTRACT

A practically complete analysis of Pd I is given, based on previous analyses. The electron structures are d^{10} , d^9s , $6s$, $7s$, $8s$ (part of) d^8s^2 (incomplete) d^95p , d^8sp and d^96p (parts of), d^95d , d^96d (almost complete).

The presence of an unidentified level k_1 is discussed and it is shown that the only explanation within the Hund theory is that k_1 is a hyperfine structure component of $5d^3P_1$. Such an assignment presents very great difficulties.

THE ARC spectrum of palladium has played a considerable part in the development and correction of the Hund theory of atomic spectra. It was partially analyzed by Beals¹ and, later, more completely by McLennan and Smith² and by Bechert and Catalan.³ About the time when McLennan was engaged on the analysis, there appeared Hund's⁴ paper, on the correlation between components of terms and the components of the limit terms on which they are built. This circumstance was unfortunate because the accuracy of the theory was quite naturally accepted by McLennan and the naming of the levels of the spectrum was carried out to agree with that theory instead of with the usual criteria, intensities and Zeeman effects. A little later Hund's book⁵ was published; and, in it, McLennan's analysis of Pd I appeared as the most conclusive evidence for the theory of limits. That theory has since been proved to be correct in only a few trivial cases.⁶ The analysis of Pd I has been only partially corrected in a paper on Ag II by McLennan and McLay⁷ and by Shenstone.⁸ The present designation of terms was communicated to Gibbs and White and was used by them in their paper⁹ on Cd III.

The following analysis is based on the numerical analyses of McLennan and Smith, and Bechert and Catalan. A considerable number of new terms has been found, some of which can be identified as second series members of the d -electron series. The spectrum in the ultraviolet has been measured, and new lines have been found by long exposures throughout the whole visible and ultraviolet.

As much information as possible has been collected in the term table.

	51285.0	2 or 3 lines are spark lines
	56168.4	2 or 3 lines used elsewhere

The 6 levels rejected from McLennan and Smith's list are all founded on lines observed by them in the underwater spark or in absorption in palladium vapor. These lines are all either spark lines or lines which have not been identified as palladium lines in any other source.

Of the 3 levels rejected from Bechert and Catalan's list, one is founded on spark lines, and the other two give only three combinations and of those, two in each case are lines otherwise used in the analysis. Those two levels are therefore possible but extremely improbable.

1. *Determination of the term types.* The information from which the term types may be determined consists of intensities of lines and Zeeman effects. For the low multiplets, the intensities¹⁰ give sufficient evidence that Bechert and Catalan's selection of terms was correct. The intensity diagram (Figure 1) demonstrates this result. Beals' Zeeman effect measurements must also be considered. These measurements are not altogether satisfactory since they are in some cases inconsistent. I have remeasured some of the ultra-

¹⁰ The intensities are Meggers' estimates and are somewhat different from those used in Table III of the paper, Phil. Mag. 8, 765 (1929).

violet lines, and from all the evidence available have calculated the probable values of the g -factors for a considerable number of terms. They are not to be considered as having an accuracy of better than about 3%. It is worth notice that the g -values would hardly permit of a choice between $5p^3D_1^0$ and $5p^1P_1^0$ although the evidence of the intensity diagram is reasonably certain.

The terms of prefix $5d$ are all from old levels. Intensities again suffice to determine the types unambiguously except perhaps for the two levels of $J=0$. The lower of the two levels has been chosen as 3P_0 because its combinations with triplet terms are considerably stronger than those of the higher level. In Ag II the equivalent levels in my analysis have both been found by Blair (to be published shortly) to be false and a new 3P_0 has been found which agrees in position and characteristics with the level chosen in Pd I. No very probable 1S_0 has been found in Ag II. The terms of prefix $6d$ were identified partly from intensities and partly from series extrapolation. In some cases they are doubtful levels and are followed by a question sign. In addition there are the terms of prefix $6s$, $7s$, $8s$, $9s$ which will be discussed below; and a large number of unidentified or doubtfully identified high odd levels. The designation of one level as k is carried over from Bechert and Catalan and the level is discussed below.

2. *Structures.* From the atomic number (46) of Pd it can be predicted that the spectrum should have low terms from the structures $4d^{10}$, $4d^95s$, $4d^85s^2$; and, from the general relations amongst similar structures in other spectra, their relative energies can be roughly predicted. Such a prediction is in agreement with the discovery of 1S_0 as the lowest term, 3D , 1D as the next and 3F as the next. The relatively high position of the 3F and, therefore, of all other terms based on $4d^85s$ makes the spectrum very much less complicated than Ni I in which $3d^94s$ and $3d^84s^2$ are of practically equal energy and importance. Except for a^3F and a^3P_2 no terms founded on $4d^85s$ can be definitely identified although a few high odd terms probably do belong to that structure.

3. *Limits.* All terms based on the ion $4d^9$ are prefixed by the symbols which indicate the quantum numbers of the one electron whose change of condition is responsible for the emission of spectral lines. Amongst the even terms it is possible to pick out directly three members of the series ns^3D^1D . A calculation of a Ritz formula then allows the prediction of the position of higher terms. The $8s^3D_3$ and the doubtful $9s^3D_3$ were found in this way. The series was then recalculated using the $6s$, $7s$, $8s$ terms. The limit of this series is $4d^9\ ^2D_{2\frac{1}{2}}$ of Pd II and the addition of 3529, known from Pd II, yields $4d^9\ ^2D_{1\frac{1}{2}}$. Those terms are given at the end of the table, together with $4d^85s\ ^4F_{4\frac{1}{2}}$ and $^4P_{2\frac{1}{2}}$ which were used to calculate the Rydberg denominators of a^3F_4 and a^3P_2 . The separation of the 2D limit is so great (3529) that even the $5p$ terms break up naturally into two groups corresponding to the components of 2D . This effect is very much more in evidence in the higher terms where we find the groups much closer together and separated by about 3500 wave numbers. In spite of such evidence of practically complete jj coupling, the intensities of the lines indicate at least as close an approach to

LS coupling as occurs amongst the lower levels. The $6d$ group of terms is new and almost complete. Its combinations with the $5p$ group give the diffuse lines in the visible and near ultraviolet previously unassigned. In particular, the two lines $\lambda 4020$ and $\lambda 4098$ which are given in the tables as reversed are in reality double lines and belong to this group. Part of one of these lines is unassigned though it would fit well as the prohibited combination $5p^3F_3^0 - 6d^3G_5$. There is therefore some doubt of the naming of 3G_5 .

The Rydberg denominator of every level whose limit is known is given in the term table. The values of these numbers for the $5d$ and $6d$ terms form confirmation of the accuracy of the calculation of the series limit.

The Ritz formula calculated from the terms $6s$, $7s$ and $8s^3D_3$ is

$$T = 67236 - T^1 = 67236.0 - \frac{R}{(n + 0.47681 - 2.037 \times 10^{-6}T^1)^2}$$

4. *High odd terms.* The wave-length list was extended as far into the ultraviolet as possible in the hope that the terms from the structure $4d^96p$ could be found and give some evidence concerning the still rather unsatisfactory theory of limits. A large number of levels was found in the proper energy range but in most cases there is insufficient evidence on which to classify them. There are undoubtedly numbers of odd levels of the structure $4d^85s5p$ in that same region and they naturally add to the difficulty. An attempt has been made to classify by means of Zeeman effects, but this also was not very successful. Some possible levels of the latter structure are indicated in the term table, the evidence being mainly Zeeman effect and intensity of combination with the term a^3F . A number of rather strong sharp lines in the region around λ 3000–3200 have been used to form these terms and there remain a few such lines unidentified.

5. *The level k_1 .* The designation k_1 for the level 54825.9 found by Bechert and Catalan has been retained as a distinguishing mark because of the very peculiar nature of that level. It is an even level of $J=1$ or 2 (but almost certainly 1) and it makes 5 exact combinations, all of which are diffuse.¹¹ It is distant from $5d^3P_1$ only 3.2 wave numbers and all of its combinations occur with those terms with which $5d^3P_1$ combines strongly. There are no other diffuse lines in Meggers' list except $\lambda 4631.37$, which is triply assigned.

There are three possible origins for the level k_1 : (1) A term of the system $4d^9nx$; (2) A term of the system $4d^85s\ nx$; (3) A hyperfine structure component of $5d^3P_1$. The first possibility may be eliminated by the observation that all terms of that structure which could have such an energy have been discovered. The second possibility reduces to a consideration of $4d^85s^2$ only, since all other even configurations yield terms much too high. The configuration d^8s^2 contains only one level of $J=1$. It is a 3P_1 level, but an examination of the analogous spectra Ni I, and Pt I and the spectrum Pd II demonstrates that k_1 is about 10,000 wave numbers too far above 3F_4 and 3P_2 . There is

¹¹ The line $\lambda 4816.27$ is of the same character as the other k_1 lines on Meggers' plates and has been so labelled in the wave-length list.

a remote possibility that the level is 1D_2 but it is at least 5000 wave numbers too high and it does not combine with either 1F_3 or 1D_2 . The third possibility, that k_1 is a hyperfine structure component of $5d^3P_1$, appears to be extremely improbable. There is certainly no expectation that a single level in a whole spectrum should show a structure of 3.2 units and that level one not involving an s -electron at all. If it is hyperfine structure, then the hyperfine structure is wider than the fine structure since $^3P_2-^3P_1$ is only 2.2 units.

I believe that the level k_1 is the only level yet found in any spectrum which cannot be logically explained on the Hund theory; but a single exception is sufficient to indicate that there is a factor which is yet to be considered. It would be of great interest to examine the Zeeman effect of a group of lines involving the levels $5d^3P_2$, 3P_1 and k_1 . The fields produced by an ordinary magnet are sufficient to produce the beginnings of a Paschen-Back effect of the three levels if they have the necessary structural affiliation.

I would like to point out in this connection that the type of analysis which has been carried out since the development of the Hund theory is unlikely to give anything but confirmation since the theory is assumed correct to start with. But that theory has been shown to be incorrect in one part, the prediction of limits, and it is possible that it is either incomplete or incorrect in other details. There is, of course, no doubt of the essential correctness of the theory.

The wave-length table (Table III) contains all the identified lines of Pd I and, in addition, the few remaining unidentified lines of any strength. The intensities are the estimates of Dr. Meggers except for a short range from $\lambda 3700$ to $\lambda 4500$ and a number of newly observed lines for which I have made estimates on about the same scale. As usual, Dr. Meggers has been extremely kind in placing at my disposal considerable unpublished data.

For convenience in visualizing the energy relations in the spectrum, a diagram of electron configurations is given in Fig. 2.

Fig. 2. Diagram of the energies of the electron configurations of Pd I. The last electron only is given except for structures based on 8 d electrons for which the characteristics of two electrons are given.

INTENSITY MEASUREMENTS IN THE SPECTRUM
OF NICKEL AND COBALT

BY L. S. ORNSTEIN AND T. BOUMA

PHYSICAL LABORATORY OF THE UNIVERSITY OF UTRECHT

(Received June 2, 1930)

ABSTRACT

Quantitative intensity measurements have been carried out in the Ni I and Ni II, and the Co I spectrum. The spectrographic outfit for the intensity measurements consisted of a stigmatic concave grating mounting used with step weakeners, and a Hilger E 1 used with the method of slit width variation. The *summation rules* have been tested both for *multiplets* and *supermultiplets*, also the intensity ratio for singlets and triplets, doublets and quartets. Serious divergencies have been found everywhere. In the Ni II spectrum an extension of the summation rules to supermultiplets gives better results in several cases. Intensity tables are given of the lines measured.

QUANTITATIVE intensity measurements have been carried out in the nickel I and II and the cobalt I spectrum. In the Ni I spectrum the analysis of Becher and Sommer¹ has been utilized; later on also the very extensive analysis by Russell, obtained through the courtesy of Professor Harrison.² For Ni II the analysis has been given by Shenstone;³ for Co I by Catalan and Bechert.⁴

In the Co II spectrum no intensity measurements have been carried out, the classified multiplets⁵ being situated in the far ultraviolet where intensity measurements meet with special difficulties.

Although the material used was the purest Ni and Co that could be obtained, the Ni contained some Fe, and the Co some Fe and Ni as impurities.

THE EXPERIMENTAL METHODS

In the first measurements for the Ni I spectrum an image of the light source through step-reducers was formed on the slit of a stigmatic concave grating-mounting; the line intensities was determined by the usual method.⁶ For the subsequent investigation a Hilger E 1 quartz-spectrograph was used. The density curves were obtained by the method of variable slit width.⁷

Frequently the photometer curves of two or more lines lying close together coalesced. In such cases it is necessary to change the photometer curve accurately point for point into the intensity curve of the complex of

lines. The same thing is done for a neighbouring isolated line. It may be assumed that the shape of the intensity curve for all these lines is the same^s and that therefore the intensity curve of the complex can be analysed into a few separate curves of this shape.

THE FIRST MEASUREMENTS

The Ni I quintet $z^5G^0 - e^5F$ was photographed with the above mentioned concave grating in second order. The results will be found in Table I, and for 0.95 amp. also in an intensity scheme (Table II).

TABLE I. *Intensities of the lines of the $z^5G^0 - e^5F$ multiplet of Ni I.*

Line λ	Intensity		Line λ	Intensity	
	1.4 amp.	0.95 amp.		1.4 amp.	0.95 amp.
4900.97	1	~ 1	4714.416	100	100
4874.803	1.1	~ 1	4686.209	11	11
4814.59	0.95	~ 1	4648.656	40	44
4786.541	38	41	4604.990	27	25
4756.529	26	29	4600.364	10	9.5
4715.757	22	24.5	4592.532	17	16

TABLE II. *Intensity scheme for the $z^5G^0 - e^5F$ multiplet of Ni I.*

Statistical Weight	5	7	z^5G^0 9	11	13	Sum	Quotient
3	9.5					9.5	3.2
5	11	16				27	5.4
e^5F 7	~ 1	24.5	25			50.5	7.2
9		~ 1	29	44		74	8.2
11			~ 1	41	100	142	12.9
Sum	21.5	41.5	55	85	100		
Quotient	4.3	5.9	6.1	7.7	7.7		

According to the summation rule the quotients in Table II ought to be equal. The divergencies are serious, as will be seen. Self-reversal cannot be the cause of this divergency for it would diminish the contrasts, whereas the divergencies lie in the opposite direction.

Although in the case under consideration the summation rule does not determine the intensity of each line separately, it gives the ratio of the extreme diagonal terms; this ought to be 27:91 i.e. 29.7:100. As this is a sensitive test, the intensity ratio between these two lines has been measured several times. (Table III).

TABLE III.

Current	Int. proportion
2.4	10. 9:100
1.4	10. 15:100
1.4	9.9 :100
0.95	9.3 :100
0.95	9.6 :100

^s L. S. Ornstein and M. Minnaert, Zeits. f. Physik 43, 404 (1927).

As blending with impurity lines is out of question, the experimental ratio 9.6:100 differs from the theoretical 29.7:100.

In order to get more facts the measurements have been continued with the Hilger E 1 in the ultraviolet. Here fairly large regions could be photographed at once and with a sufficient dispersion.

The current used was the smallest possible (about 0.45 amp.) A preliminary examination with 0.80 and 0.45 amp. showed that difference between the intensities found for these currents is comparatively small.

A few intensity measurements have also been carried out in an arc with a pressure of 50 and 28 cm of air. These also did not show any appreciable difference for the intensity. Therefore the definitive measurements for Ni I and CO I have been carried out with a current of 0.45 amp. in air.

In the Ni II investigation a Leyden jar was charged by the secondary tension of an induction coil. The spark discharge of the jar took place via a self-induction between two small bars of nickel. Variations of the conditions of discharge could not be used here. Only, to get a current of small density, a Leyden jar of the smallest possible capacity was chosen.

THE DEFINITIVE MEASUREMENT

In each of the three spectra mentioned a region has been chosen in which a number of multiplets, suitable for intensity measurements was situated. The region was situated for Ni I between 2900 and 3800Å, for Ni II between 2450 and 3770Å for Co I between 2500 and 4500Å.

Besides the multiplets the intensities of all the lines appearing in the photographs have been measured. In the tables the intensities found by analysis of the photograms have been marked (1) when the analysis was certain, (2) when it was less certain and (3) when the analysis was very doubtful. Intensities marked (4) are inexact, owing to the slight density and the great influence of the irregularities which the photometer curve shows in the unexposed plate for that case. The tables are the least complete on the side of the largest wave-lengths where the dispersion was so small that several lines had to be omitted. The experimental facts have been used for testing: (1) the multiplet summation rules; (2) the supermultiplet summation rules; and (3) the intensity ratio for singlets and triplets, doublets and quartets. Generally the theoretical expectations are not fulfilled. For this reason we have limited our measurements to the spectral regions given below. Perhaps our material will be of some help in developing the intensity rules for the complicated spectra.

THE Ni I SPECTRUM

Besides the quintet $z^5G^0 - e^5F$ already mentioned 13 multiplets have been examined.

The intensities in horizontal and vertical direction have been formed and the quotients of intensity sums and statistical weights have been calculated in the same way as has been done for $z^5G^0 - e^5F$, the results are collected in Table IV.

TABLE IV. Intensity quotients in multiplets of Ni I.

No.	Multiplet Designation	Quotients									
1	$a^3D - y^3D^0$	35	28	17		36	29	16			
2	$a^3F - y^3D^0$	11.7	6.2	5.8		9.1	3.9	3.8			
3	$a^3D - y^3F^0$	34	18	7.4		25	25	23			
4	$a^3F - y^3F^0$	10	7.5	3.2		2.4	7.0	7.8			
5	$a^3F - z^3G^0$	3.2	6.5	4.2		2.6	8.5	6.1			
6	$a^3P - v^3D^0$	0.4	0.4	0.4		0.8	0.8	0.7			
7	$a^3D - z^3G^0$	4.5	1.7			6.2	2.3				
8	$a^3D - z^3F^0$	31	22	10		30	28	24			
9	$a^3D - z^3D^0$	23	[25]	18		[37]	29	10			
10	$a^3F - z^3D^0$	22	21.6	10.3		23.3	10.1	6.6			
11	$a^3F - z^3F^0$	21	12.1	5.9		12	17.6	6.7			
12	$a^3D - z^3P^0$	70	51	33		49	28	14			
13	$a^3F - z^3P^0$		4.3	2.4		3.1	1.4				
14	$z^5G^0 - e^5F$	3.2	5.4	7.2	8.2 12.9	4.3	5.9	6.1	7.7	7.7	

The quotients [25] and [37] have been deduced from sums containing a line, ordered doubly, so that they are too high by an unknown amount.

Only the multiplet 6 is in accordance with expectation (and multiplet 3 in one direction). In the case of all other multiplets the summation rules do not apply. In the case of the incomplete multiplets, e.g. $2^5G^0 - e^5G$ it also appears from the intensities of the lines present that the summation rule will not hold.

Supermultiplets. If singlet, triplet and singlet-triplet intercombinations are taken together, no satisfactory results are reached (Table V).

TABLE V. Supermultiplet sums and quotients of intensity.

Statistical weight	3	a^3D 5	7	a^1D 5	Sum	Quotient	
y^3D^0	3 5 7	61 47	43 55 48	40 71	39 20 43	143 162 162	48 32 23
y^1D^0	5	8.7	23		72	103.7	21
Sum		116.7	169	111	174		
Quotient		39	34	16	35		

In the same way the quotients in Table VI are found.

TABLE VI.

Combinations	Quotients							
$a^3D, a^1D - z^3D^0, z^1D^0$	24	[35]	28	22	[38]	32	11	42
$a^3D, a^1D - y^3F^0, y^1F^0$	34	25	7	15	25	25	28	25
$a^3D, a^1D - z^3F^0, z^1F^0$	36	33	10	33	30	39	31	46

Again, when either the multiplets or all the lines, coming from the same term, are taken together the summation rules do not apply, e.g. for y^5D^0 : (Table VII).

TABLE VII.

Statistical weight	5	a^3F 7	9	3	a^3D 5	7	a^1D 5	Sums	Quotient
γ^3D^0	35			61	43		39	178	59

z^3P^0	146.6	140	100
Sum	596.1	974.7	918.4
Quotient	199	195	131

Here the divergencies are smaller than for the separate multiplets. Still it is not very likely that the few multiplets still wanting will be able to equalize the quotients.

According to Mack⁹ the multiplets arranged in Table X belong together. Equal quotients are not obtained in this way either. Especially the first column shows a great divergence.

Finally we shall consider the ratio between the sums of the intensities for the corresponding singlet-triplet multiplets. When intercombinations are absent a ratio of 1:3 can be expected.¹⁰ The values found for our case are shown in Table XI; the last column contains the ratios after dividing the intensities by the fourth power of the frequency. There is a fairly great difference between the experimental and the theoretical ratios. However, fairly strong intercombinations are present in all 5 cases.

Table XII contains the intensities for all the lines in the spectral region investigated; an (arbitrary) intensity of 100 has been awarded to the line 3524.543.

THE NI SPARK SPECTRUM

Eight doublets and 4 quartets have been measured; the quotients of intensity sums and statistical weights are found in Table XIII.

TABLE XIII.

Multiplet Designation		Quotients							
1	$a^4D^1-d^4F^1$	—	1.2	1.0	1.3	—	1.7	1.4	1.65
2	$a^2P^1-b^2P$	5	4.95			5.8	4.55		
3	$a^2P^1-b^2D^1$	0.5	0.05			0.07	0.5		
4	$a^4G^1-d^4F^1$	1.6	2.0	2.35	2.9	1.9	1.7	2.0	1.8
5	$a^2G^1-d^2F^1$	1.6	2.1			1.7	1.3		
6	$a^4F-d^4F^1$	2.85	1.9	1.5	1.15	1.85	1.4	1.7	1.7
7	$a^2F-d^2F^1$	1.6	1.0			1.3	1.2		
8	$a^2D^1-d^2F^1$	0.87	0.85			1.3	1.1		
9	a^2G-b^2F	0.6	0.9			0.5	0.7		
10	$a^2D-a^2D^1$	2.8	1.1			2.6	1.3		
11	a^2D-a^2F	0.47	0.04			0.15	0.4		
12	$a^4P^1-a^4D^1$	3.2	2.15			5.0	3.25	0.85	—

For some of the multiplets the disagreement with the summation rule is not very great, for others, however, the divergencies are wide, e.g. in the case of Nos. 3 and 11, where the diagonal terms are by far the weakest.

Adding up the doublet and quartet systems and the intercombinations, we get the quotients of Table XIV.

TABLE XIV.

Combinations	Quotients											
$a^4D^1, a^4D^1-d^4F^1, d^2F$	—	1.5	1.65	1.3	0.9	0.85	—	1.7	1.4	1.65	1.7	2.0
$a^4G^1, a^2G^1-d^4F^1, d^2F^1$	1.6	2.0	2.35	2.9	1.6	2.1	1.9	1.7	2.0	1.8	1.7	1.3
$a^4F, a^2F-d^4F^1, d^2F^1$	2.85	1.9	1.7	1.16	1.6	1.15	1.85	1.4	1.7	1.8	1.3	1.5

If we add the multiplets which in the quartet systems start from a^4D^1 , we find the quotients shown in Table XV.

TABLE XV.

Statistical weight	a^4D^1				a^4F^1				a^4G^1				Sum	Quotient
	1	2	3	4	2	3	4	5	3	4	5	6		
d^4F^1														
2					3.7	2.0			3.2				8.9	4.5
3	3.4	0.3				2.3	3.5		2.5	3.5			15.5	5.2
4			4.0				3.3	2.6		3.3	6.1		19.3	4.8
5				6.6				5.8			3.8	10.7	26.9	5.4
Sum	—	3.4	4.3	6.6	3.7	4.3	6.8	8.4	5.7	6.8	9.9	10.7		
Quotient	—	1.7	1.4	1.7	1.9	1.4	1.7	1.7	1.9	1.7	2.0	1.8		

There is comparatively little difference between these quotients. If we add to them the small number of intercombinations that occur, we find $4.5|5.4|5.7|5.4|$.

In the same way we find:

TABLE XVI.

	a^2D^1			a^2F		a^2G^1		Sum	Quotient
	2	3		3	4	4	5		
d^2F^1									
3	2.6			3.8	0.9	4.8		12.1	4.03
4		3.4			4.0	1.9	6.6	15.9	3.98
Q	1.3	1.1	1.3	1.2	1.7	1.3			

These results are satisfactory if the occurring intercombinations are added, the quotients become 4.03 and 4.12.

In our material these two multiplets are the only ones which start from the same level. The quartet $a^4P^1 - a^4D^1$ has the same original level as number of intercombinations. But we cannot conclude from these measurements, as there are other lines in the part of the spectrum that has not been examined which start from the same level. However, it is remarkable that the intensity ratios of this quartet are largely corrected by the additions of the intercombinations.

TABLE XVII.

	a^4P^1			a^2F^1		a^2D			
	1	2	3	3	4	2	3	Sum	Quotient
1	2.7	0.5				0.5		3.7	3.7
2	2.3	2.0		0.4		1.0	0.4	6.1	3.6
a^4D^1 3		4.0		0.9	1.1	1.3	3.9	11.2	3.7
4			2.6		2.7		7.2	12.5	3.1

In combining lines with a common final level we again meet with the difficulty that our materials are not complete; various lines that ought to be included do not occur in the spectral region that has been examined. Still the influence of the additions of the other intensities can be seen from Table XVIII.

TABLE XVIII.

	a^2D			a^2P^1			a^4P^1		
	2	3		1	2		1	2	3
a^2F	0.3	1.25	b^2D^1	0.07	1.05	a^4D^1 5	6.5	2.6	
a^2D^1	5.2	3.8	b^2P	5.8	9.1	a^2D^1	1.7	2.7	
a^4D^1	2.8	11.5	b^4D^1	1.2		a^2F		1.2	
a^4F	0.5	0.3	b^4P	1.0	2.8	a^4F	0.3		
			a^2F		0.2				
Sum	8.8	16.85	b^2F		0.4	Sum 5	8.5	6.5	
Quotient	4.4	5.6				Quotient 5	4.3	2.2	
			Sum	8.07	13.55				
			Quotient	8.1	6.8				

We have considered also the intensity ratio for doublet-quartet systems.

TABLE XIX.

Combinations	Ratio
$a^2D - d^2F^1$ and $a^4D^1 - d^4F^1$	1:1.6
$a^2G^1 - d^2F^1$ and $a^4G^1 - d^4F^1$	1:2.4
$a^2F - d^2F^1$ and $a^4F - d^4F^1$	1:2.4

The last column is found after division by ν^4 . The ratio 1:2 is found only approximately; this cannot be attributed to the occurring intercombination lines (3, 2 and 0 respectively) as in the last case where they do not occur, the divergency is the same as in the other two.

In the following intensity table (Table XX) an intensity of 100 has been awarded to line 2437.884.

TABLE XX. *Intensities of the lines of Ni II.* Intensities marked (1) are certain, (2) less certain, (3) doubtful, (4) inexact because of small intensity and irregularities in the plates.

λ (Kayser)	λ (I.A.)	Int.	λ (Kayser)	λ (I.A.)	Int.	λ (Kayser)	λ (I.A.)	Int.

THE CO I SPECTRUM

In Table XXI the computed quotients are given for all the multiplets measured. The indication of the multiplets is that of Catalan and Bechert. The quotients with question marks between brackets are too large, owing to lines which are ordered doubly in the multiplets to which they refer. In quartet No. 30 one of the lines in the multiplet itself has been ordered doubly; 4 quotients had therefore to be left out.

TABLE XXI

No.	Level	Quotients											
4	F^1-D^1	40	46					29	34				
5	F^1-D^2	108	56					73	42				
6	$F^1-\bar{F}^1$	35	34					26	41				
7	$F^1-\bar{F}^2$	75	67					102	47				
8	F^1-G^1	72	61					77	90				
9	F^1-G^2	98	47					95	85				
15	ϕ^2-d^3	6.1	6.5	7.5	8.0			10.3	8.3	15.5			
19	f^1-d^1	99	80	78	41			89	83	41	13		
20	f^1-d^2	16	16	15	10			10	12	11	6		
21	f^1-d^3	20	20	16	11			23	15	8	4.4		
22	f^2-d^1	35	76	71	52			29	54	51	38		
23	f^2-d^2	155	115	83	51			135	78	62	18		
24	f^2-d^3	4.4	4.8	7.4	7.6			5.7	5.9	6.4	2.4		
25	$f^1-\bar{f}^1$	89	72	[82]	30			75	70	60	[55]		
26	$f^1-\bar{f}^2$	59	30	22	17			38	36	29	17		
28	$f^2-\bar{f}^1$	[2.3]	2.4	3	7.7			1.0	[2.1]	3.5	8		
29	$f^2-\bar{f}^2$	132	118	[98]	49			157	[127]	79	49		
30	$f^2-\bar{f}^3$	11	—	11.5	—			21	—	12	—		
31	f^1-g^1	33	23	18	15			50	28	25	18		
32	f^1-g^2	38	30	10	7			25	30	29	14		
34	f^2-g^1	4.4	7.5	9.6	6.5			0.5	3.8	8.7	17.6		
35	f^2-g^2	142	89	61	26			88	97	93	80		
36	f^2-g^3	2.2	5.5	2.8	3.8			3.0	3.9	6.2	4.6		
81	$\phi^1-\phi^1$	1.6	2.6	2.6	3.3	4.4	1.1	2.2	2.2	3.0	3.4	5.3	
82	$\phi^1-\phi^1$	2.9	3.0	3.8	2.8	2.3	12	4.3	4.6	3.7	1.5	7.5	8.2

None of the 25 multiplets follows the summation rule. Neither are equal quotients obtained when doublet and quartet systems are taken together with their intercombinations. For a few of these systems the results are found in Table XXII.

TABLE XXII.

Terms	Quotients											
f^1, F^1 and g^2G^2	101	57	39	44	59	7	25	32	34	22	112	148
f^1, F^1 and g^1G^1	73	66	33	23	19	15	50	28	31	18	77	91
f^1, F^1 and $\bar{f}^2-\bar{F}^2$	78	73	65	33	53	46	38	38	34	17	150	83
f^1, F^1 and d^2-D^2	109	58	16	16	16	19	10	14	12	6	74	51

If we take together the lines which originate from the same level we find the quotients of Table XXIII.

TABLE XXIII.

Term	Quotient			
g^1	38	31	28	21
G^1	110	84		
g^2	181	133	120	33
G^2	138	84		

Although for the level mentioned here the system is complete, the results are not appreciably better than for the separate multiplets; sometimes (for G^1) even worse.

For the other terms the system is incomplete; of these only for d^3 a considerable improvement is found. Here we combine f^1-d^3 , f^2-d^3 , F^1-d^3 and p^2-d^3 and find the quotients 31, 32, 32 and 28. However, p^1-d^3 , p^2-d^3 and P^1-d^3 could not be taken into account as they did not occur in spectral region we investigated.

TABLE XXIV.

Final level	Quotients			
f^1	315	293	235	144
f^2	431	488	413	264
F^1	467	450		

Finally we can add all the lines with a common final level. In each of these 3 cases a few systems of lines are wanting (2, 2 and 3 respectively), but it is highly improbable that the quotients given, which have been derived from 16, 16 and 13 lines respectively, would be greatly influenced by these.

For the ratio of intensities of doublet and quartet systems the following values (after division by ν^4) are tabulated here:

TABLE XXV.

Multiplet	Ratio
F^1-D^1 and f^1-d^1	1:2
F^1-D^2 and f^1-d^2	1:0.22
$F^1-\bar{F}^1$ and $f^1-\bar{f}^1$	1:2.1
$F^1-\bar{F}^2$ and $f^1-\bar{f}^2$	1:0.4
F^1-G^1 and f^1-g^1	1:0.3
F^1-G^2 and f^1-g^2	1:0.22

In 4 of the 6 cases the doublet is even stronger than the quartet. This cannot be ascribed to the existing intercombinations as the divergencies in the case of the systems F^1-D^2 and F^1-G^1 , where the intercombinations are weak, is much the same as in that of F^1-F^2 and F^1-G^2 with their strong intercombinations. Whereas the division by ν^4 yields a fairly correct ratio in 2 cases, it increases the error in the other 4 cases.

All the intensity values found are shown in Table XXVI in which an intensity of 100 has been awarded to the line 3334.151.

TABLE XXVI. *Intensities of the lines of Co I.* Intensities marked (1) are certain, (2) less certain, (3) doubtful, (4) inexact because of small intensity and irregularities in the plates.

THE EFFECT OF THE MOTION OF THE NUCLEUS ON THE SPECTRA OF Li I AND Li II

By D. S. HUGHES AND CARL ECKART

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received July 7, 1930)

ABSTRACT

The wave equation for a system of N electrons (mass m) and one nucleus (mass M) is set up and solved approximately. If $W(m)$ are the energy levels for $M = \infty$, the energy levels for finite M are $(\mu W(m)/m) + \Delta W$, where $\mu = mM/(m+M)$ and ΔW is calculable.

In case $N=2$ or 3 , ΔW is zero except for P levels. For these it is given by Eq. (13), which is derived on the assumption that the wave function is a polynomial of hydrogen functions, each with its own effective nuclear charge. The values of the latter previously determined by one of the authors are used in comparing the calculation with Schüler's experimental data on Li II, $\lambda 5485$ and Li I, $\lambda 6708$. The agreement is satisfactory and eliminates one objection to Schüler's interpretation of $\lambda 5485$.

IT IS well known that the effect of the motion¹ of the nucleus on the spectra of hydrogen and ionized helium may be accounted for by replacing m , the mass of the electron, by $\mu = mM/(m+M)$, M being the mass of the nucleus. This simple procedure does not suffice for elements of more than one electron, and as an effect observed in the spectrum of lithium has been ascribed to this cause, a theoretical discussion of the expected effect seems in order. Some of the results obtained are applicable to the general case of N electrons, others only to Li I and Li II.

1. GENERAL

The kinetic energy operator for a system of N electrons and one nucleus is

$$T = -\frac{\hbar^2}{4\pi^2} \left\{ \frac{1}{2\mu} \sum_{k=1}^N \nabla_k^2 + \frac{1}{M} \sum_{(k,i)} \nabla_k \cdot \nabla_i + \frac{1}{2(M+Nm)} \nabla^2 \right\} \quad (1)$$

in which

$$\nabla_k = i \frac{\partial}{\partial x_k} + j \frac{\partial}{\partial y_k} + k \frac{\partial}{\partial z_k}$$

$$\nabla = i \frac{\partial}{\partial X} + j \frac{\partial}{\partial Y} + k \frac{\partial}{\partial Z}$$

where x_k, y_k, z_k are the rectangular coordinates of the k^{th} electron in a system whose origin is located at the moving nucleus, and (X, Y, Z) are the coordinates of the center of mass of the atom in another system of arbitrary fixed origin. The quantities m, M , and μ have the significance already defined.

¹ This term will be used to describe the translatory motion of the nucleus about the center of mass of the atom, as distinguished from the nuclear "spin".

The wave equation is thus

$$\{T + V(x) - W\}\psi = 0 \quad (2)$$

where V is the potential energy of the atom and is independent of the coordinates of the center of the mass. For simplicity, it may be assumed that the latter is at rest, so that ψ will also be independent of (X, Y, Z) .

If it be assumed that the characteristic values $W(m)$ and solutions $\psi(m)$ of Eq. (2) are known for $M = \infty$ (stationary nucleus), the effect of the finiteness of M may be approximately resolved into two parts:

- a. M is replaced by μ in $W(m)$ and $\psi(m)$.
- b. The energy level is displaced by an additional amount ΔW given by

$$\psi(m)\Delta W = H'\psi(m) = -\frac{h^2}{4\pi^2 M} \sum_{(k,j)} \nabla_k \cdot \nabla_j \psi. \quad (3)$$

The perturbed energy value is thus $W(\mu) + \Delta W$. The statement (b) assumes that there is no degeneracy other than that conditioned by the rotational symmetry of the problem (degeneracy in the magnetic quantum number).

These two effects may be treated independently; for the first,² it is necessary to investigate the dependence on μ of the characteristic values of the equation

$$-\frac{h^2}{8\pi^2 \mu} \sum_{1 \rightarrow N} \nabla_k^2 \psi + [V(x) - W(\mu)]\psi = 0. \quad (4)$$

Since $V = \sum (Ze^2/r_k) - \sum (e^2/r_{jk})$ is a homogeneous function of degree -1 in the 3 N variables³ the calculation may be made rigorously without knowing ψ : on introducing new variables $x_k' = \alpha x_k$, $y_k' = \alpha y_k$, $z_k' = \alpha z_k$, where $\alpha = \mu/m$, and noting that $V(x) = \alpha V(x')$, Eq. (4) becomes

$$-\frac{h^2}{8\pi^2 m} \sum_{1 \rightarrow N} \Delta_k'^2 \psi + [V(x') - W(\mu)/\alpha]\psi = 0.$$

Hence

$$W(\mu) = \alpha W(m). \quad (5)$$

Since α is less than 1, this causes a general contraction of the spectrum relative to that of an atom whose nucleus has infinite mass. This may be called the normal effect, since it is the only effect in the case of the simplest spectra.

The specific effect ΔW cannot be evaluated without some assumption regarding $\psi(m)$. It is simplest to assume it as a polynomial of hydrogen functions, each with a different nuclear charge determined by the variational method of calculating characteristic values.⁴ The coefficients of the poly-

² The calculation is merely an extension of that usually given for hydrogen.

³ This is true only if the electron spin energy is not included in V .

⁴ C. Eckart, Phys. Rev. **36**, 149 (1930). It is not known whether such a polynomial is really a good approximation to $\psi(m)$ or not, but it may be shown to yield approximately correct values for the energy. There is also some justification for its use in a perturbation calculation, but the magnitude of the error introduced is uncertain. Experience would seem to show that it is smaller than if the true nuclear charge was used in each hydrogen function; cf. W. Heisenberg, Zeits. f. Physik **39**, 511 (1926). Whatever may be the theoretical status of effective nuclear charges, it should be remarked that the values of Z_1 and Z_2 used in these calculations have not been determined *ad hoc* but are the results of independent calculations made without reference to the present problem.

nominal are determined so that $\psi(m)$ has the proper permutational symmetry. Calculations based on this assumption follow for the cases of two and three electron systems.

2. TWO ELECTRON SYSTEMS

The wave function may be approximated by

$$\psi = [u(1)v(2) \pm v(1)u(2)]/2^{1/2} \quad (6)$$

in which u is the characteristic function of the $1s$ state, v of the excited state (n, l), and the numerals designate the variables of the two electrons. The effective nuclear charge for the function u is to be taken approximately equal to Z , the true nuclear charge. If v represents a $2p$ state, its effective nuclear charge is approximately $Z_2 = Z - 1.0$. The precise theoretical⁴ values for Li II, 2^3P are $Z_1 = 2.98$, $Z_2 = 2.16$. The upper sign in Eq. (6) is for the singlet level, the lower for the triplet. The perturbation operator in this case is simply

$$H' = -h^2 \nabla_1 \cdot \nabla_2 / 4\pi^2 M$$

and

$$\Delta W = \iint \psi^* H' \psi d\tau_1 d\tau_2.$$

On integrating by parts with respect to the variables 2,

$$\Delta W = (h^2/4\pi^2 M) \iint (\nabla_1 \psi) (\nabla_2 \psi^*) d\tau_1 d\tau_2;$$

noting that

$$\int (\nabla u) u^* d\tau = \frac{1}{2} \int \nabla |u|^2 d\tau = 0,$$

and making use of Eq. (6), this reduces to

$$\Delta W = \pm (h^2/4\pi^2 M) \left| \int u^* \nabla v d\tau \right|^2. \quad (7)$$

This integral will be evaluated at the end of the next section.

3. THREE ELECTRON SYSTEMS

In this case, it may be well to take account of the permutation degeneracy directly: there are three independent characteristic solutions

$$\psi_1 = v(1)u(2)u(3), \quad \psi_2 = v(2)u(3)u(1), \quad \psi_3 = v(3)u(1)u(2) \quad (8)$$

and

$$H' = - (h^2/4\pi^2 M) (\nabla_1 \cdot \nabla_2 + \nabla_2 \cdot \nabla_3 + \nabla_3 \cdot \nabla_1). \quad (9)$$

The function u again represents the $1s$ state, this time with Z_1 approximately equal to $Z - 0.3$, while v , in the case of the configuration $(1s)^2 (2p)$, has the approximate nuclear charge $Z_2 = Z - 2.0$. In the case of Li I, 2^3P , the theo-

retical values are⁴ $Z_1=2.69$, $Z_2=1.02$. The Eq. (3) is to be replaced by the three equations

$$\begin{aligned} a\Delta W &= aA + bB + cB \\ b\Delta W &= aB + bA + cB \\ c\Delta W &= aB + bB + cA \end{aligned} \quad (10)$$

in which

$$\begin{aligned} A &= \iiint \psi_i^* H' \psi_i d\tau_1 d\tau_2 d\tau_3 \\ B &= \iiint \psi_i^* H' \psi_j d\tau_1 d\tau_2 d\tau_3. \end{aligned} \quad (11)$$

The quantities A and B are real and independent of i and j since the operator H' is symmetric in the three sets of coordinates. The determinant of Eqs. (10) has one single root $\Delta W = A + 2B$ and one double root $\Delta W = A - B$. The former belongs to a state which is excluded by the Pauli principle, the latter to the actual doublet state.

On substituting Eqs. (8) and (9) into (11), it is found that

$$A = 0, \quad B = - (h^2/4\pi^2 M) \left| \int u^* (\nabla v) d\tau \right|^2,$$

so that ΔW has the same functional form as in the case of a two electron system.

This integral is readily evaluated: as a generalization of a well-known equation, it is readily shown that

$$\begin{aligned} - (h^2/4\pi^2 m) \int u^* (\partial v / \partial x) d\tau &= (W_u - W_v) \int x u^* v d\tau \\ &= e^2 (Z_1 - Z_2) \int (x u^* v / r) d\tau, \end{aligned} \quad (12)$$

W_u and W_v being the Balmer term-values associated to u , Z_1 and v , Z_2 , respectively. By a slight generalization of the methods used to derive the selection principles for spectral lines⁵ it may be shown that both integrals on the right vanish unless the values of the azimuthal quantum numbers of u and v differ by exactly one unit. As u represents the $1s$ state, ΔW will therefore vanish unless v represents a p state, and the specific effect is shown only by P levels (in this approximation at least). The displacement of these is found to be

$$\Delta W = \pm \frac{128}{3} \frac{m}{M} R_\infty Z_1^5 Z_2^5 n^3 (n^2 - 1) \frac{(Z_1 n - Z_2)^{2n-4}}{(Z_1 n + Z_2)^{2n+4}}$$

⁵ A. Sommerfeld, *Wellenmechanischer Ergänzungsband*, p. 92. (Vieweg, Braunschweig, 1929).

in which R_∞ is the Rydberg constant, $2\pi^2me^4/h^2$, and n is the true principal quantum number. The increment of energy will be negative for the three electron system and the triplets of the two electron system, positive for the singlets.

4. COMPARISON WITH OBSERVED EFFECTS

H. Schüler⁶ has proposed an interpretation of the hyperfine structure of the Li II line 2^3P-1^3S , $\lambda 5485$, according to which the nucleus of Li (6) has no angular momentum while that of Li (7) has $1/2$ unit. On the basis of his analysis it is possible to calculate the displacement of the Li (6) lines from the position which the Li (7) lines would occupy if there were no nuclear spin. These displacements are given in the last column of Table I. The three values should be identical to at least two significant figures, so that the differences are to be ascribed to errors, either in measurement or interpretation, or in both.

TABLE I.

	Li (6)	Li (7)	$\Delta\lambda$
$^3P_0-^3S$	5484.10	5483.81	0.29A
$^3P_2-^3S$	5485.02	5484.69	0.32
$^3P_1-^3S$	5485.65	5485.31	0.34

Using the values of $Z_1=2.98$, $Z_2=2.16$ Eq. (13) yields 0.256 A for the displacement produced by the specific effect, while Eq. (5) yields 0.071 A for the normal effect. The resultant is 0.327 A, the Li (6) line being to the long wave-length side of Li (7). This value is in excellent agreement with those of Table I. This calculation therefore supports part of Schüler's interpretation of this line though the present considerations would not defend it against attacks from other directions.⁷

Schüler and Wurm⁸ have also found that the lines 2^2P-1^2S of Li I, $\lambda 6708$, are doubled, with a separation of 0.15A. This has been confirmed by one of us (H), the observed separation being between 0.155 and 0.160A. Assuming the nuclear spin to be $1/2$ for Li (7), the structure due to this cause should be only 0.03-0.04A wide. The effect has therefore been interpreted as being primarily due to the motion of the nucleus.

The calculated values, using $Z_1=2.69$ and $Z_2=1.02$ (cf. Section 4) are 0.087A for the normal effect and 0.036A for the specific, a total of 0.123A. The agreement is as good as might be expected, since the difference between observed and calculated is of the order of the unresolved spin structure.

We would like to conclude from these results that Schüler's interpretation of $\lambda 5485$ is correct, but, in view of the results Harvey and Jenkins⁷ have obtained from the band spectra of lithium, the question had best be left open.

ELECTRONIC STATES IN THE VISIBLE HALOGEN BANDS

BY ROBERT S. MULLIKEN*

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received July 7, 1930)

ABSTRACT

It is shown on the basis of theoretical considerations that the well-known visible iodine absorption bands and the analogous bands of the other halogens almost certainly cannot correspond to a ${}^1\Sigma \leftarrow {}^1\Sigma$ transition as hitherto supposed. It is concluded that they belong to a ${}^3\Pi_{0u} \leftarrow {}^1\Sigma_g^+$ transition, with a case *c* ${}^3\Pi_0$ state whose Λ -type doubling is so wide that the state is split into two separate states which simulate a ${}^1\Sigma_u^+$ and a ${}^1\Sigma_u^-$ state. The observed bands involve however only the state which behaves like ${}^1\Sigma_u^+$, the ${}^1\Sigma_u^-$ -like state and the ${}^3\Pi_1$ and ${}^3\Pi_2$ states being unknown. The classification ${}^3\Pi_0$ really has little meaning, one needs for case *c* here a classification in which only Ω values and symmetry properties (+ or -, *g* or *u*) are significant. According to the above interpretation, the upper level of the halogen bands is paramagnetic, this is in harmony with certain magnetic phenomena observed with these bands. Electron configurations for the normal and excited states are suggested in the case of fluorine.

TWO identical atoms in the same 2P state¹ are capable, as one finds by applying the relations obtained by Wigner and Witmer,² of giving only the following set of molecular states: ${}^1\Delta_g$, ${}^3\Delta_u$, ${}^1\Pi_u$, ${}^1\Pi_g$, ${}^3\Pi_u$, ${}^3\Pi_g$, ${}^1\Sigma_g^+$, ${}^1\Sigma_g^-$, ${}^1\Sigma_u^+$, ${}^3\Sigma_u^+$, ${}^3\Sigma_u^-$, ${}^3\Sigma_g^-$. As we shall see, this is almost certainly⁵ in conflict with the current interpretation of the visible absorption bands of iodine and the analogous bands of the other halogens as ${}^1\Sigma$, ${}^1\Sigma$ transitions. The argument is as follows.

For convenience we shall speak in terms of the *chlorine* bands, since our knowledge is more well-rounded for these than for the bands of the other halogens. What is said is intended to apply to all the halogens, since there can scarcely be a doubt that the bands of the four molecules are all of the same type. In respect to some properties, the iodine bands are better known than the chlorine bands, but we shall feel free to apply this knowledge also to the latter. (1) That the *normal state* of Cl_2 is ${}^1\Sigma$ seems assured by the fact that chlorine gas is diamagnetic (Br_2 and I_2 are also known to be diamagnetic in the *liquid* state). This conclusion is strongly supported by a study of

* Fellow of the John Simon Guggenheim Memorial Foundation, now in Leipzig.

¹ For the prediction of the possible molecular states as given above, the division of the 2P normal state into ${}^2P_{3/2}$ and ${}^2P_{1/2}$ substates does not matter, by the "normal state" of the atom we mean either ${}^2P_{3/2}$ or ${}^2P_{1/2}$ or both.

² E. Wigner and E. E. Witmer, *Zeits. f. Physik* **51**, 883 (1928). The designations Σ^+ and Σ^- used here correspond to Wigner and Witmer's Σ and Σ^1 (also to their 0 and 0'). The subscripts *g* and *u* (gerade and ungerade) mean "even" and "odd". In the case of odd (even) states the electronic factor of the wave-function ψ does (does not) change sign on reflection in the midpoint of the line joining the nuclei. Σ_g , Π_u , Δ_g are respectively the same as Σ_+ , π_- , Δ_+ of Wigner and Witmer, while Σ_u , Π_u , Δ_u are the same as their Σ_- , Π_- , Δ_- .

possible electron configurations for the normal molecule.³ (2) That this $^1\Sigma$ state is either a $^1\Sigma_g^+$ or a $^1\Sigma_u^-$ state is shown by the fact that the rotational levels with odd values of K have the greater statistical weight.^{4,5} Either $^1\Sigma_g^+$ or $^1\Sigma_u^-$ is capable,—see above,—of being derived from two normal atoms.¹ Whether or not the normal states of the halogens *actually are* so derived is not essential to the present argument, but is nevertheless of interest. By extrapolation from the known vibrational levels of the normal state, as in the method of Birge and Sponer, one gets, for I_2 , Br_2 and Cl_2 , values of the energy of dissociation which agree well with the supposition that dissociation does give normal atoms.¹ Also, since all excited states of the atoms (including $F^+ + F^-$) lie high above the normal level, it is improbable that any of these could give normal atoms. (3) A consideration of possible electron configurations consistent with $^1\Sigma_g^+$ and $^1\Sigma_u^-$ shows that only $^1\Sigma_g^+$ is reasonable for the normal state of the halogens.⁶ But even if we should

³ A $^3\Pi_1$ state would also be diamagnetic, but such a state is very unlikely to be the normal state, since the correspondence $^3\Pi_2$ would probably also exist and be lower, assuming case *a* coupling, $^1\Sigma$ is also by far the most probable normal state on the basis of a study of electron configurations.

⁴ That the odd levels have the greater weight is shown in the case of Cl_2 by the band analysis of A. Elliot (Proc. Roy. Soc. 123A, 629, 1929). In the case of Br_2 an analysis of the bands is lacking, while in I_2 no alternations in intensity have been detected. If we represent the complete wave function ψ as a product of three factors, $\psi = \psi_{el}\psi_{rot}\psi_{nu-spin}$, then we know (a) ψ must on theoretical grounds (cf. R. S. Mulliken, Trans. Faraday Soc. No. 102, 25, Part II Nov. 1929) be antisymmetrical in the nuclei (An)⁵; (b) for the levels with greater statistical weight in any homonuclear molecule, $\psi_{nu-spin}$ is always symmetrical in the nuclei (Sy), for odd values of K in a Σ state, ψ_{rot} is always An . For the odd K values, therefore, in Cl_2 ψ_{rot} is An , $\psi_{nu-spin}$ is Sy , hence, since ψ itself must be An , ψ_{el} must be Sy . This is the case for either a Σ_g^+ or a Σ_u^- state. (The possibility of Σ^- states was overlooked in the writer's article just cited, and led to some erroneous conclusions in regard to O_2 , whose normal state is now known to be $^3\Sigma_g^-$.)

⁵ That the complete ψ must be An for a molecule whose nuclei contain each an odd number of (protons plus electrons), as theoretically predicted by Hund (cf. R. S. Mulliken, Ref. 4), is contradicted by the experimental results on N_2 , where ψ is Sy although the nucleus is composed of 21 particles (14 protons, 7 electrons). The most probable reformulation is that ψ has to be An if the nucleus of each atom contains an odd number at *protons* (and Sy if it contains an even number), regardless of the electrons. Since both the old and the new conditions for an An ψ are fulfilled for the Cl atom, it seems safe to take this for granted. If, however, the contrary should be true, the following results would hold: the normal Cl_2 molecule is $^1\Sigma_u^+$ or $^1\Sigma_g^-$ (both are improbable on the basis of a consideration of electron configurations), and dissociates giving at least one highly excited atom (this would hardly be possible to reconcile with data on the vibrational levels (cf. section (2) in the text above)), the excited molecule would then probably be $^1\Sigma_g^+$ or Σ_u^- , either of which is derivable from normal atoms¹, in agreement with section (5) in the text.

⁶ It is highly probable that the normal state of F_2 is a $^1\Sigma_g^+$ state with essentially the following electron configuration: $1s^2 2p^2 2s^2 3p^2 3d^2 2p\pi^4 3d\pi^4$. Possible $^1\Sigma_u^-$ states are derivable from $\dots 2p\pi^3 3d\pi^3 nx\sigma^2$ (n and x anything not already present) and $\dots 2p\pi^4 3d\pi^3 3p\pi$. The first of these (probably with $nx\sigma^2 = 4f\sigma^2$) might be derived from two normal atoms, but would surely be higher and be more unstable than the $^1\Sigma_g^+$ configuration mentioned above. The second ($\dots 3p\pi$) could probably be obtained only from one normal F atom and one excited atom with a $3p$ electron; the energy of excitation of the latter would be so great that it practically certainly could not give the normal state of F_2 . Analogous arguments apply to the other halogens.

assume ${}^1\Sigma_u^-$, we should still come to the conclusion that the halogen bands here under discussion cannot be a ${}^1\Sigma, {}^1\Sigma$ transition. (4) Assuming that the normal state is ${}^1\Sigma^g$ and that the coupling relations in both states correspond to Hund's cases *a* or *b*, the *excited state* can only be one of the following:⁷ ${}^1\Sigma_u^+$, or ${}^1\pi_u$, or ${}^3\Sigma_u^+$, or ${}^3\Pi_u$. (5) According to Franck's well-known interpretation of the convergence limits of the halogen bands, the excited state dissociates without question into two normal atoms,—more accurately, into one ${}^2P_{1/2}$ and ${}^2P_{1/2}$ atom. (6) Since a ${}^1\Sigma_u^+$ state cannot possibly be obtained from two normal atoms (cf first paragraph), the excited state cannot possibly be ${}^1\Sigma_u^+$, and the bands therefore cannot be of the ${}^1\Sigma, {}^1\Sigma$ type. The possibilities ${}^1\Pi_u$, ${}^3\pi_u$, and ${}^3\Sigma_u^+$ for the excited state remain, since all are consistent with dissociation into normal atoms.

None of the interpretations ${}^1\pi \leftarrow {}^1\Sigma$, ${}^3\pi \leftarrow {}^1\Sigma$, and ${}^3\Sigma \leftarrow {}^1\Sigma$ appear easy to reconcile with the observed structure of the bands, which (in Cl_2 and I_2 , F_2 and Br_2 not having been investigated as yet) consists definitely only of one *P* and one *R* branch, each composed of single lines arranged exactly as in the case of a ${}^1\Sigma, {}^1\Sigma$ transition. The absence of a *Q* branch probably rules out the possibility of a ${}^1\Pi$ upper level. ${}^3\Pi$ also seems unlikely unless its combinations with ${}^1\Sigma$ are restricted, say, to one component of the ${}^3\Pi_0$ level (see below). In favor of ${}^3\Sigma_u^+$ is the fact that in a ${}^3\Sigma \leftarrow {}^1\Sigma$ transition only a *P* and an *R* branch are expected. But one would expect these to consist of wide doublets as in the ${}^1\Sigma \leftarrow {}^3\Sigma$ atmospheric oxygen bands.⁸ That the observed lines are single seems hardly reconcilable with a ${}^3\Sigma, {}^1\Sigma$ combination. One might of course suppose that the ${}^3\Sigma$ rotational triplets are so narrow as to be unresolved, but, especially for the heavier halogens, this is wholly contrary to theory, as well as to experimental data on doublet separations in ${}^3\Sigma$ states. Another conceivable explanation would be that in the ${}^3\Sigma$ level the components with $J=K\pm 1$ are widely separated from those with $J=K$ and that, for unknown reasons, only combinations of the levels with $J=K$ with levels of the ${}^1\Sigma_g^+$ normal state are observed. This would give simple *P* and *R* branches in agreement with experiment, but it is very far-fetched.

An escape from these difficulties is to be found by noting a fact whose consequences have hitherto not been fully appreciated. In the excited states of the halogen molecules, the energies of dissociation *D* are very small ($D=0.55$ volts for I_2 , 0.39 volts for Br_2 , 0.23 for Cl_2 , and by extrapolation from the other halogens, about 0.1 volts for F_2); they are roughly about equal to the doublet separations between the ${}^2P_{1/2}$ and ${}^2P_{3/2}$ sublevels of the normal states of the halogen atoms (I, 0.94 volts, Br, 0.45 volts, Cl, 0.11 volts, F, 0.05 volts). From these figures we can conclude that, especially in the heavier halogens, the influence of the electric axis on the electron orbits

⁷ The following selection rules apply if both states correspond to coupling cases *a* or *b* or intermediate cases: $\Delta\Lambda=0, \pm 1$; Σ^+ terms combine with Σ^+ but never with Σ^- terms; in homonuclear molecules, even terms (*g*) combine only with odd terms (*u*). Quintet states are ruled out, for the excited state, by the fact that the latter dissociates into normal atoms (cf. list of possible states in first paragraph).

⁸ R. S. Mulliken, Phys. Rev. 32, 880 (1928).

is not large enough to break down, at any rate not at all completely, the coupling of each atomic L vector with its S vector. The quantum numbers $L_1, S_1, J_1, L_2, S_2, J_2$ of the two atoms still retain their significance to a considerable extent in the molecule. J_1 and J_2 give respectively quantum numbers Ω_1 and Ω_2 (or M_1 and M_2) which represent their projections on the electric axis. The only electronic quantum number which is significant for the molecule as a whole is Ω ($\Omega = |M_1 + M_2|$) Λ and S for the molecule as a whole are practically meaningless as quantum numbers; λ 's of individual electrons are even more completely lacking in significance; nevertheless Λ, S , and λ values can be formally assigned by imagining the nuclei pushed closer together. This coupling case can be classified as a form of Hund's case c ; in another form which has been more discussed, the molecule as a whole has an L and an S , which are strongly coupled to give a resultant J^a , which in turn gives a projection Ω .

For the *normal* states of the halogen molecules, where the D values are moderately large (assuming dissociation into two $^2P_{1/2}$ normal atoms, they are, $D = 1.53$ volts for I_2 , 1.96 volts for Br_2 , 2.54 for Cl_2 , and by extrapolation, about 3.1 volts for F_2), we may assume Hund's case a , or in I_2 perhaps a case intermediate between a and c .

In dealing with the present weak-binding form of case c , it seems best to designate different electronic states simply by numbers giving their Ω values (0, 1, 2, etc.), together with a superscript $+$ or $-$ when $\Omega = 0$ and a subscript g or u in the case of homonuclear molecules in order to designate certain symmetry properties of their ψ functions. Here g and u have the same meaning as in cases a and b . So do $+$ and $-$, but for convenience we may here define 0^+ and 0^- states as follows: in 0^+ states the even-numbered rotational levels ($J = 0, 2, \dots$) are even (in the sense of Kronig) or positive (in the sense of Wigner and Witmer), while the odd-numbered levels are odd or negative;⁹ in 0^- states the relations are reversed.¹⁰

As selection rules in case c here we have only the following: $\Delta\Omega = 0, \pm 1$; $\Delta J = 0, \pm 1$; $g \rightleftharpoons u$; even or positive combine only with odd or negative rotational levels. The intensity relations in the P, Q , and R branches should be governed, just as in case a , by the Hönl and London intensity formulas.¹¹ For example, transitions between a 0 and a 1 state should show a P , a strong Q , and an R branch. (The 1 state should have Ω -type doubling, vanishing with zero rotation, and similar to the Λ -type doubling for a $^1\Pi$ state in cases a and b ; and the P and R branches should make connection with one component of each Ω -type doublet, the Q branch with the other). Transitions

⁹ The words "even" [R. de L. Kronig, *Zeits. f. Physik* 50, 351 (1928)] and "positive" (Wigner and Witmer, ref. 2, 867, footnote) are here synonymous; likewise for "odd" and "negative".

¹⁰ For a discussion of the behavior of $^3\Pi_0$ states in the passage from case a to case c , cf. J. H. Van Vleck, *Phys. Rev.* 33, 501-2 (1929). Van Vleck points out that the a and b sets of sublevels of $^3\Pi_0$ behave like a $0^+, 0^-$ pair (similar to $^1\Sigma^+$ and $^1\Sigma^-$). In regard to notation use of $+$ and $-$ cf. ref. 2.

¹¹ H. Hönl and F. London, *Zeits. f. Physik* 33, 803 (1925) Cf. R. S. Mulliken, *Phys. Rev.* 29, 391, (1927) for discussion and applications.

between two 0 states should show only a *P* and an *R* branch, just as for $^1\Sigma$, $^1\Sigma$ transitions in case *a*. This latter fact, taken in connection with the selection rule even \rightleftharpoons odd for rotational terms, shows that only combinations between two 0^+ states, or between two 0^- states, but not those between a 0^+ and a 0^- state, are capable in case *c* of giving rise to spectrum lines.¹² In case, however, there should be a departure from the conditions of case *c* toward those of case *a*, *Q* branch combinations between a 0^+ and a 0^- state may also be expected (cf. next paragraph).

Let us now consider as a typical example, for a range of cases from *a* to *c*, a transition which in case *a* would be classified as $^3\Pi_0$, $^1\Sigma$. The $^3\Pi_0$ state has two rotational levels for each *J* value ($J=0, 1, 2, \dots$); these may be considered as derived from two electronic sublevels of $^3\Pi_0$, namely from a 0^+ and a 0^- sublevel.¹¹ In case *a*, we may probably expect a *P*, a *Q*, and an *R* branch in a $^3\Pi_0$, $^1\Sigma$ combination. For a $^1\Sigma^+$ type of $^1\Sigma$ state, the *P* and *R* branches come from the 0^+ levels of the $^3\Pi_0$, the *Q* branch from the 0^- levels. In the passage to case *c*, the *P* and *R* branches remain, but the *Q* branch 0^- , 0^+ combination should gradually fade out, while at the same time the 0^- levels may become widely separated¹¹ from the 0^+ levels.

In both limiting cases (*a* and *c*), and probably also in intermediate cases, the rotational energy for the $^3\Pi_0$ states is given by an expression of the form $E = \text{const.} + B_v J(J+1) + \dots$. The same expression for E' also holds for all electronic states in case *c*, as well as in case *a*.

We are now in a position to interpret the halogen bands from a more general viewpoint than that adopted at the beginning of this paper. Their observed structures show that they are a $0 \leftarrow 0$ transition; more specifically, since we have seen that the lower state is in all probability a $^1\Sigma_g^+$ and since they consist of *P* and *R* branches, we conclude that they are $0_u^+ \leftarrow 0_g^+$. As we have already seen, the 0_u^+ state cannot correspond to a $^1\Sigma_u^+$ state, since such a state is not derivable from normal atoms. In the list of states derivable from normal atoms (cf. first paragraph of paper), only one 0_u^+ state is to be found, namely the 0^+ component of the $^3\Pi_u$ state,¹³ and we therefore conclude that the upper level of the halogen bands is of this type. The absence of a *Q* branch corresponding to the 0^- component of $^3\Pi_u$ can be understood (cf. preceding paragraph) in view of the fact that we expect case *c* coupling here for the 0_u^+ state. It may even be that the 0_u^- state is much more unstable than the 0_u^+ , so that the corresponding band system $0_u^- \leftarrow 0_g^+$ (*Q* branches) may consist only of a continuous region: furthermore, it may be that this system is very weak.—It should be emphasized that the classification of the 0_u^+ level as belonging to $^3\Pi$ has only a formal meaning, since

¹² This is analogous to, but not (except in singlet states) identical with the rule that in combinations between Σ states only Σ^+ , Σ^+ and Σ^- , Σ^- are possible.

¹³ The other 0 states derivable from two equal 2P atoms are, 0^- from $^3\Pi_u$, 0^+ and 0^- from $^3\Pi_g$, two 0_g^+ states and one 0_u^- state corresponding to the three $^1\Sigma$ states (one of the 0_g^+ states is the normal $^1\Sigma_g^+$ state of the molecule), and two 0_u^- and one 0_u^+ state from the two $^3\Sigma_u^+$ states and the one $^3\Sigma_u^+$ state respectively. A $^3\Sigma^+$ state gives in case *c*, as is easily shown, one 0^- and one 1 state; a $^3\Sigma^-$ state, one 0^+ and one 1 state (cf. later paper).

quantum numbers Λ and S are not defined here in case c . Physically, this 0_u^+ level may have little resemblance to a ${}^3\Pi_0$ ordinary level of case a .

By application of the methods of Wigner and Witmer, it is possible to predict, for a loosely-bound case c molecule as here, the molecular states which can be derived from each of the individual combinations ${}^2P_{1\frac{1}{2}}+{}^2P_{1\frac{1}{2}}$, ${}^2P_{1\frac{1}{2}}+{}^2P_{\frac{1}{2}}$ and ${}^2P_{\frac{1}{2}}+{}^2P_{\frac{1}{2}}$.¹⁴ The results are, for the case of two equal atoms in the same 2P state: ${}^2P_{1\frac{1}{2}}+{}^2P_{1\frac{1}{2}}$ gives $3_u, 2_g, 2_u, 1_u, 1_g, 1_u, 0_g^+, 0_u^-, 0_g, 0_u^-$; ${}^2P_{1\frac{1}{2}}+{}^2P_{\frac{1}{2}}$ gives $2_g, 2_u, 1_g, 1_u, 1_g, 1_u, 0_g^+, 0_u^+, 0_g^-, 0_u^-$; and ${}^2P_{\frac{1}{2}}+{}^2P_{\frac{1}{2}}$ gives $1_u, 0_g^+, 0_u^-$.¹⁵ The fact that only ${}^2P_{1\frac{1}{2}}+{}^2P_{\frac{1}{2}}$ is capable of giving a 0^+ state is in satisfying agreement with the experimental fact that the upper level of the halogen bands, here classified as 0_u^+ , is actually derived from ${}^2P_{1\frac{1}{2}}+{}^2P_{\frac{1}{2}}$. The lower, 0_u^+ , level is probably derived from ${}^2P_{1\frac{1}{2}}+{}^2P_{1\frac{1}{2}}$, although ${}^2P_{1\frac{1}{2}}+{}^2P_{\frac{1}{2}}$ or ${}^2P_{\frac{1}{2}}+{}^2P_{\frac{1}{2}}$ is not theoretically impossible, and also experimentally not yet absolutely excluded.

Some additional items of evidence having a bearing on the above interpretation of the halogen bands will now be mentioned. (1) The fact that the I_2 bands show a Faraday effect¹⁶ may be cited as evidence in favor of a paramagnetic upper level. Now it can be shown that a case c molecular state with $\Omega=0$ and derived from a ${}^2P_{1\frac{1}{2}}$ plus a ${}^2P_{\frac{1}{2}}$ atom *should* be paramagnetic; and that in the passage to a case a ${}^3\Pi_0$ state, the paramagnetism must increase.¹⁷ Of course, as Kemble has pointed out,¹⁸ a magnetic moment might be developed by rotation, even in a ${}^1\Sigma$ state; and in a loosely bound molecular state such as we have here, a rather large moment might be developed in this way through uncoupling of the atomic J vectors from the electric axis. But it seems hardly likely that the small rotational energies involved in the case of the observed band lines are large enough to give rise to the magnetic effects observed. (2) The fact that the fluorescence of the I_2 bands is (in part) quenched by a magnetic field¹⁸ is further evidence in favor of a paramagnetic upper level. (3) If the bands are ${}^3\Pi_0 \leftarrow {}^1\Sigma$ one might expect their intensity to increase markedly in going from F_2 to I_2 , since the intensity of intersystem combinations is extremely weak for the lightest atoms like He,

¹⁴ The rules which govern this case, and some applications, will be discussed in a subsequent paper.

¹⁵ The group of states here predicted corresponds, as of course it must if correct, in a one to one manner to the set of states predicted by the Wigner and Witmer method for cases a and b , and given at the beginning of this paper. E.g., 3_u from ${}^2P_{\frac{1}{2}}+{}^2P_{\frac{3}{2}}$ corresponds to $\Omega=3$ of ${}^3\Delta_u$ at case a .

¹⁶ Cf. E. C. Kemble, Nat. Research Council Bulletin on Molecular Spectra, p. 347.

¹⁷ To get a state with $\Omega=0$ from ${}^2P_{\frac{1}{2}}+{}^2P_{1\frac{1}{2}}$, we must assume the J of the ${}^2P_{1\frac{1}{2}}$ atom oriented with a projection $M=\pm 1/2$ on the electric axis, the J of the ${}^2P_{\frac{1}{2}}$ atom with a projection $M=\mp 1/2$. Since Landé's g factor is $4/3$ for ${}^2P_{1\frac{1}{2}}$ and $2/3$ for ${}^2P_{\frac{1}{2}}$, the total magnetic moment parallel to the electric axis is $(4/3 \times 1/2 - 2/3 \times 1/2) = 1/3$ Bohr magneton. This holds for the limiting case of very loose coupling of the atoms. In a case a ${}^3\Pi_0$ state, we have a magnetic moment of ± 2 magnetons parallel to the electric axis due to the spin ($S=1, \Sigma=-1$) and of ∓ 1 magnetons due to $\Lambda=1$, making a net result of 1 magneton parallel to the electric axis. (The magnetic moment component perpendicular to the electric axis also in some cases contributes to the paramagnetism.)

¹⁸ W. S. Steubing, Ann. d. Physik 58, 55 (1919).

and increases with the intensity of the coupling of L and S vectors. The fact that the upper level is case c 0^+ rather than case a $^3\Pi_0$ should however probably diminish this effect since the molecular S loses its meaning in case c , but it might well still exist to a more or less marked extent, since it is likely that case a is more nearly approached in the lighter than in the heavier molecules. In the halogen bands in which we are interested, the spectrum consists of two parts, namely the bands proper (relatively weak), and the continuum (stronger). Since the continuum corresponds to transitions with r near r_e'' , and since we probably have case a for $r=r_e''$, the upper level should function here as a true $^3\Pi_0$ level, and the strong variation of intensity with molecular weight which is to be expected for intersystem combinations should make itself evident here. Experimentally the intensity of the bands proper increases rather rapidly in the order F_2 to I_2 , but this is at least partly explainable in terms of the $U'(r)$ and $U''(r)$ curves by means of the Franck idea as applied by Condon. So far as can be judged from available data,¹⁹ the absorption in the continuum is however also much stronger for iodine than for chlorine, and this effect cannot be attributed to the nature of the $U(r)$ curves. This relation is therefore in harmony with our expectation.

(4) If one assigns the electron configuration $1s\sigma^2 2p\sigma^2 3p\sigma^2 3p\pi^4 3d\sigma^2 3d\pi^4$ to the $^1\Sigma_g^+$ normal state of F_2 , and assumes that the excited state corresponds to $\dots 3d\pi^3 4f\sigma$ one removes the only known exception²⁰ to the writer's λ conservation rule (formerly called " $\sigma_{l,r}$ conservation rule") for molecule formation (Of course the configurations given here have a physical meaning only, for small values of the distance between the nuclei.) The writer is, however now inclined to believe that this rule has not much significance. For Cl_2 the corresponding configurations are $\dots 3s\sigma^2 4p\sigma^2 3p\pi^4 4d\sigma^2 4d\pi^4$ and $\dots 4d\pi^3 5f\sigma$ and so on.

¹⁹ Cf. International Critical Tables Vol. V, p. 269. The nature of the intensity relations can be judged by the following values of the absorption coefficient K in the equation $I = I_0 e^{-Kl}$ (l = length of absorbing path in cm, in gas or vapor). For the maximum of the continuous absorption, K has the following values: Cl_2 , $K \sim 2$ for $p = 760$ mm at $0^\circ C$; Br_2 , $K \sim 1.36$ for $p = 66$ mm at $16^\circ C$; I_2 , $K \sim 0.21$ for $p = 0.17$ mm (reduced to $0^\circ C$) and $K \sim 0.77$ for $p = 1.67$ mm (reduced to $0^\circ C$). If we assume the validity of Beer's law (but the data on I_2 show that it does not hold) we get for $p = 1.67$ mm at $0^\circ C$, $K \sim 0.013$ for Cl_2 , $K \sim 0.033$ for Br_2 , $K \sim 0.77$ for I_2 .

AN INTERPRETATION OF PRESSURE AND HIGH VELOCITY VAPOR JETS AT CATHODES OF VACUUM ARCS

BY KARL T. COMPTON

MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received July 1, 1930)

ABSTRACT

Tanberg's conclusion, that the evaporating vapor from the cathode of a copper vacuum arc escapes with a temperature of about $500,000^{\circ}\text{K}$, which is based upon measurements of the repulsive force against the cathode, is shown to be unnecessary. The observed pressures can reasonably be explained in terms of the "accommodation coefficient" of the incoming Cu ions. It is thus shown that the observed pressures are accounted for if the positive ions retain about 2 percent of their incident kinetic energy after neutralization at the cathode.

IN A recent article in this journal¹ Mr. R. Tanberg has described some very pretty experiments on arcs drawn from a copper cathode *in vacuo*, which prove that there is a pressure of approximately 0.015 gm per ampere against the cathode, and a pressure of similar order of magnitude against an insulated vane placed about 2 cm in front of the cathode. These pressures, which were corrected for several minor disturbing influences, indicate the existence of material ejected with high speed from the cathode, and the experiments showed that this material is uncharged. Since copper evaporated from the cathode during the experiments, Tanberg identified the jet of high speed material with this stream of evaporated copper. The measurements of the amount of evaporation and the magnitude of the pressure led him thus to the conclusion that this vapor jet has a velocity of the order of $16(10)^5$ cm/sec and hence that "the temperature existing at the cathode spot determined from the velocity of the cathode vapor is of the order of $500,000^{\circ}\text{K}$ " "far in excess of even the most extreme temperatures ever measured in connection with any physical phenomena of any duration!" In view of the importance of this conclusion, if true, in the interpretation of arc cathode phenomena, it is important critically to examine Mr. Tanberg's work and the possibility of some less startling interpretation of his experimental results.

There is one part of Mr. Tanberg's calculations which shows entire failure to comprehend the nature of the electrostatic forces exerted on a cathode by the intense field at its surface. These are attractive forces, tending to pull the cathode toward the discharge, and Mr. Tanberg adds an estimated force of this type to the observed repulsion, to obtain the "corrected" repulsive force due to the reaction of the escaping vapor stream. He fails to note, however, that this strong field at the cathode arises from the positive ion space charge near it, that the attraction is mutually between cathode and

¹ Tanberg, Phys. Rev. 35, 1080 (1929).

ions, and that when the ions strike the cathode, they deliver momentum to it at a rate which exactly counterbalances the electrostatic pull which they exerted on it before impact. That this follows from the elementary relation $\int F dt = \int m dv$ is obvious and has long been recognized in such problems.² Thus this electrostatic correction should not have been made. It happens, however, to be only a few percent of the observed force, so that correction of this error does not essentially alter the evidence for a high speed stream of neutral particles escaping from the arc cathode.

There is, however, a phenomenon occurring at cathodes which appears quite adequate to explain Mr. Tanberg's results without invoking any unusual temperature of cathode spot. It is the occurrence of an "accommodation coefficient" of positive ions, as recently reported to the American Physical Society by Dr. Van Voorhis and the writer.³ Positive ions, on striking the cathode, become neutralized but do not, on the average, give up enough of their kinetic energy to reach thermal equilibrium with the cathode. They rebound as neutral atoms from the cathode with some fraction β of their incident kinetic energy.

Although, as we have seen, the impact of a charged ion against the cathode contributes nothing to the pressure against it (on account of the counterbalancing pull during its attraction to the cathode), nevertheless if the neutralized ion leaves the cathode with any momentum there is imparted to the cathode an equal opposite momentum. The following calculations show that this type of momentum transfer seems easily adequate to account for the pressures observed by Mr. Tanberg.

Let f be the fraction of the total current which is carried by positive ions at the cathode, and let β be the fraction of the incident energy of the ion which is retained after neutralization. β is approximately equal to $1 - \alpha$, where α is the accommodation coefficient. The arc drop in a copper arc of high current density carried in copper vapor has been shown by Nottingham⁴ to be 20.5 volts. It appears certain that the fall space in such an arc is so thin that ions make few if any collisions while traversing it.

Taking data from one of Mr. Tanberg's typical experiments (test No. 353) we calculate the following data:

Positive ion current at cathode.....	11 <i>f</i> amps
Mass of Cu ions striking cathode per sec.....	0.00724 <i>f</i> gm
Number of Cu ions striking per sec.....	7.0(10) ¹⁸ <i>f</i>
Kinetic energy of an incident ion.....	3.26(10) ⁻¹¹ erg
Total kinetic energy of ions striking per sec.....	22.8(10) ⁸ <i>f</i> erg
Total kinetic energy of neutralized ions leaving per sec...	22.8(10) ⁸ <i>f</i> β erg
Total momentum of neutralized ions leaving per sec, which is equal to the pressure on the cathode.....	5.86 <i>f</i> (β) ^{1/2} gm
If neutralized ions escape in random directions, as is likely, the resultant pressure is.....	2.93 <i>f</i> (β) ^{1/2} gm

² Duffield, Burnham and Davis, Proc. Roy. Soc. 97, 326 (1920).

³ Van Voorhis and Compton, Phys. Rev. 35, 1438 (1930).

⁴ Nottingham, J. Frank. Inst. 207, 301 (1929).

We now equate this to the observed pressure (corrected for "electrodynamical" disturbances but not for electrostatic disturbances as explained above) and obtain

$$2.93f(\beta)^{1/2} = 193.2(10)^{-3}.$$

We must now decide what value to use for the fraction f of current carried by positive ions at the cathode. Knowledge of this quantity is still woefully uncertain, even in the case which has been most studied, the mercury arc,⁵ but all indications point to a value not far from $f=0.5$. Theoretically we would like perhaps to see a smaller value, but it seems impossible to find a much smaller value experimentally, unless we strain the interpretation of results. Furthermore, the present copper arc is probably of essentially the same type as the mercury arc.⁶ So we shall provisionally assume that $f=0.5$. Solving, then, for β we find

$$\beta = 0.0174; \quad \alpha = 0.9826.$$

Thus the pressures observed by Mr. Tanberg would be accounted for if less than 2% of the incident energy of the ions were retained after neutralization. If we had assumed a smaller value of f , β would have come out larger and α smaller. The accommodation coefficient of Cu ions has never been measured, but from analogy with other ions of about the same atomic weight we might easily expect Cu ions to possess an accommodation coefficient as small as 0.9. Hence these considerations appear to give ample leeway for a reasonable explanation of Mr. Tanberg's results.

A possible objection to this theory based on the fact that Cu ions should condense on the cathode on striking it is met by the fact that their energies correspond to temperatures far in excess of the boiling temperature of the metal.

In conclusion it may be pointed out that this criticism does not alter Mr. Tanberg's basic conclusion regarding a high speed neutral vapor stream. It merely suggests an electrical mechanism for the acquiring of these speeds instead of assuming a terrifically high temperature at the cathode.

An interesting test of this interpretation is now being made by repeating Mr. Tanberg's experiments with a non-volatizing cathode of tungsten in a rare argon atmosphere. Here there is no possibility of an evaporated vapor stream like that considered by Mr. Tanberg, but the pressure effect due to the accommodation coefficient of argon ions is calculable directly from the work of Van Voorhis and Compton, combined with collector measurements to give directly the actual positive ion current.

SECONDARY EMISSION FROM METALS BY IMPACT OF
METASTABLE ATOMS AND POSITIVE IONS

BY W. UYTERHOEVEN AND M. C. HARRINGTON

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received June 16, 1930)

ABSTRACT

Experiments on the secondary electron emission from nickel electrodes due to bombardment of positive ions and metastable atoms in a neon discharge under conditions simulating those at the cathode in a glow discharge are described. Measurements with a collector movable in a direction perpendicular to a fixed plane collector give approximate values of the proportion γ of the apparent positive ion current which is actually carried by secondary electrons. Values of 15-50 percent are found depending on the experimental conditions and degree of purity of gas. A perforated plate behind which is situated a Faraday box is used to separate the effects of the ions and metastable atoms. A preponderant part of the emission is ascribable to the metastable atoms, but values of the number α of free electrons per positive ion, are found to be 14 to 20 percent, varying approximately linearly for ions of velocities of 75 to 150 volts. The secondary electrons originate at the surface of the collector with about 12.5 volts maximum initial velocity.

IN ALL theories of the cathode fall in the glow discharge there has been assumed a source of electrons at the surface of the cathode or in the immediate neighborhood of it. Generally it is supposed that these electrons are liberated from the metal by the impact of positive ions. Although the existence of this phenomenon has been established by several experimenters, direct experimental evidence under conditions simulating those at the cathode is not very extensive. Most of the determinations of the secondary emission due to ion impact have been made with ions from a Kunsman source, and have proved that the effect was rather small.^{1,2} This is what one would expect if the secondary emission depended on the potential energy of the ion. A necessary condition for secondary emission would then be that the ionization potential of the gas atom $V_i \geq 2\phi$, where ϕ is Richardson's work function.³ In accordance with this view Penning^{4,5} found for Ne ions impinging on different metals, efficiencies which were appreciably larger than those which had been found for alkali ions, and a linear variation of the number α of secondaries per incoming ion with the energy of the latter. All observers point out that α depends markedly on the surface condition of the metal and, since practically all the measurements have been done in a rather high vacuum, it might well be that under the actual conditions

of the cathode fall α is very much larger. The present work^{6,7} is an attempt to determine α under conditions as similar as possible to those at the cathode of a glow discharge, where adsorbed atoms and ions may appreciably change the properties of the metal surface.

A few years ago one of the writers,⁸ using a plane Langmuir collector in the positive column of the glow discharge, obtained current-voltage characteristics differing from those obtained by Langmuir and Mott-Smith in the mercury arc.⁹ Comparison of the measured ion current density i_m to a negatively charged collector with the value i_c , calculated from the usual space charge equation, showed differences amounting to 40–50 percent of i_m , i_m being larger than i_c . The simplest interpretation of these results was the assumption of a secondary emission from the metal up to 40–50 percent of i_m . This, however, led to a value for α of the order of magnitude 1, and it was therefore suggested that possibly metastable atoms diffusing out of the discharge contributed to the electron emission when striking the metal plate.^{10,11} This estimate of i_c was based on the assumptions underlying the derivation of the space charge equation, the most important being in this case the absence of ionization in the sheath. This introduced some uncertainty in the interpretation referred to above. Therefore different methods were devised to determine the secondary electron part in the apparent positive ion current i_m to a negatively charged electrode.

APPARATUS

Since the electrodes are continuously bombarded by positive ions of high velocity, they sputter rapidly; accordingly a set of nickel electrodes (Fig. 1) was constructed which could easily be adjusted in the different tubes used in the experimental work. The discharge was of the hot cathode type to permit a wide variation of the current density. The cathode was an oxide coated nickel cylinder, (heated by a tungsten filament inside), the anode a large nickel plate or cylinder. The main collecting electrode P was a circular nickel disk (diameter 18.2 mm) with a coplanar concentric guard ring (outer diameter 29.2 mm). The latter was supported by the cylinder L , which shielded the space within it from the discharge; the cylinder L was in turn protected on its vertical side by a glass cylinder to avoid the collecting of too large positive ion currents and subsequent distortion of the potential distribution in the main discharge. The central plate P was supported by the cylinder M , which shielded the box B from uncharged particles diffusing through the slit S between the guard ring G and the plate P . The box B supported by the nickel rod R was cylindrical in shape, closed at the top and bottom. At the center of the upper cover was a circular hole (diameter 2 mm), which was immediately under a 0.74 mm hole at the center of the plate P .

The movable cylindrical collector C was also made of nickel. The collector used in the first type of tube (i.e. cylindrical tube, which we will designate by no. 1) was somewhat simpler in construction than that used in the later type of tube (no. 2) (See Fig. 1). Cylinder no. 1 (length 10.8 mm, diameter 7.3 mm) was divided into quarters by vertical nickel partitions. The lower end was covered with fine nickel gauze, the upper end closed by a piece of solid nickel, the inner side of which was cone-shaped to reduce electron reflection to a minimum. A glass cap fitting the cylinder left only the gauze-covered end exposed to the discharge. In the course of the work, this glass cap as well as the glass tubing protecting the leading-in wire for the cylinder became coated with sputtered metal. To eliminate as far as possible

Fig. 1. Detail of collecting electrodes.

the resulting troubles the movable cylinder C_2 (diameter 4.8 mm) was fitted with a concentric guard ring E in the plane of the gauze-covered end (outer and inner diameter 11.0 and 5.4 mm respectively). Only the lower end of the guard-ring collected current, the back being protected by the glass cap enclosing the cylinder. The collector C was movable along its axis, i.e., perpendicular to the plane of the plate P , opposite to which it was placed.

The metal used in the construction of the electrodes was outgassed, before being used, by heating in vacuo to a red heat by high frequency induction currents.

Two types of tubes were used: first a cylindrical one (inner diameter 6 cm) with a bulbular enlargement at the cathode end and later a spherical one (diameter 15 cm). In the first the collectors were in the positive column and in the second in a uniform luminosity which filled the whole sphere.

During the measurements the neon gas was constantly circulating and passed through a misch-metal arc, while liquid air traps were used to avoid contamination of the neon by traces of mercury. The usual experimental technique in work of this kind was strictly followed (baking out of the tubes at high temperature while being evacuated, etc.).

EXPERIMENTAL METHODS AND RESULTS

Different methods can be applied for the measurement of the secondary emission. One, which was already referred to above, is to measure the apparent positive ion current to a negatively charged plane collector i_m , and simultaneously the thickness x of the dark space charge sheath. With the space charge equation the value of the positive ion current i_c corresponding to the potential difference between collector and space, and the thickness x may be calculated. If all the assumptions underlying the derivation of the space charge equation are satisfied, the difference $(i_m - i_c)$ gives a measure of the secondary electron emission. Due to a number of uncertain factors the values thus obtained in the earlier work were considered as provisional; the direct measurements here recorded check the order of magnitude of these earlier estimates.

First Method. Suppose the cylinder C is placed at a certain distance d from the plate and opposite to it. When C is made negative with respect to the surrounding gas, e.g., $V_c = -125v$, it will collect a certain positive ion current. The plate, originally floating, is now also made more and more negative with respect to the gas. If any secondary electrons are emitted from the plate, they will be accelerated by the electric field in the space charge layer and, after acquiring an energy corresponding to the potential of the plate with respect to the gas (potential drop in the sheath), increase the ionization in the space between the two collectors. So long as the plate is less negative than the cylinder, the electrons will not be able to run against the retarding potential in the sheath covering the cylinder. In this stage the ion current to the cylinder is slightly increasing (see Fig. 2, curve I , A to B), due to the additional ionization by the secondary electrons from the plate. When the plate potential V_P reaches V_C , there is a sudden decrease in the current i_c due to the incoming electrons, and this decrease is a measure of the secondary electrons leaving the plate P . The two principal factors to be considered in a quantitative analysis of these results, are the loss of energy of the electrons on their way from the plate to the cylinder and the decrease in intensity of the electron beam due to scattering.

Let us suppose for simplicity that the space potential in the discharge opposite to the plate is the same as the space potential in front of the cylinder. The difference in potential will actually be not more than a couple of volts, according to the theory of Tonks and Langmuir.¹² This simplification enables us to use the potentials of the cylinder and plate as measured with respect to the anode, since only the differences between V_C and V_P must be considered for the moment. If we use the extrapolated line AB (Fig. 2) as reference line,

¹² Tonks and Langmuir, Phys. Rev. **34**, 876 (1929).

the difference between its ordinate for a given value of $(V_P)_a$ and the corresponding ordinate of curve I gives the electron current collected at the cylinder. The curve I, read with respect to AB , is an integral curve, i.e., the difference for $(V_P)_a = -135v$, for instance, represents the number of electrons which on reaching the outer edge had an energy component normal to the bottom plane of the cylinder equal to or larger than $125v$. Since the potential of the plate is $(V_P)_a = -135v$, electrons are collected which have lost at most a forward component of momentum corresponding to an energy of 10 volts. Plotting the slope of the curve I, as read with respect to AB , we get a distribution curve (II, Fig. 2) of the electrons reaching the cylinder for the velocity component normal to the bottom plane of the cylinder.

Since the reception of electrons is confined to such a narrow region, say from $(V_P)_a = -112$ to about -160 in the case plotted (Fig. 2), we conclude that the electrons for this type of discharge arise at the plate P_c or very near

Fig. 2. Curve I.—Current to cylinder C as a function of the potential of the plate $(V_P)_a$ with respect to the anode. Cylinder potential $(V_C)_a = -125v$.

Curve III. Current to the plate i_P .

to it, for if appreciable numbers originated at other points of the sheath on P , the decrease in the curve would be much more gradual and extend farther to the right on the plot.

(Some objection may be raised against the use of the extrapolated line AB as zero line for the electron current reaching the cylinder. When the latter is absorbing part of the secondary electrons coming from the plate, $(V_P)_a$ more negative than $(V_C)_a$, the ionization produced by these in the space between plate and cylinder must be less than when the cylinder is reflecting the largest part $(V_P)_a$ less negative than $(V_C)_a$. When the pressure in the tube is made rather low ($p = 1 \times 10^{-2}$ mm or less) the slope of AB becomes

very small and the difference between the ordinate of AB and the curve rather large, so that this possible error must be small. In fact for pressures lower than 10^{-2} mm, the line AB is practically horizontal.)

Studying the velocity distribution curve II of Fig. 2 somewhat more closely, we notice first that the electrons start coming in when the retarding potential between cylinder and plate is about $-12.5v$. If the secondary emission is due to metastable neon atoms striking the plate, one must assume according to Oliphant¹¹ that the excess energy is transferred to the electron. Since the energy of a metastable neon atom ($2p^5.4s$) is about $16.5v$, taking for the work function of nickel $\phi_- = 4.4v$, we have for the maximum energy of the electron at the moment it leaves the plate $16.5 - 4.4 = 12.1$. If the secondary emission is due to positive ions, the maximum energy which the electron could carry away when leaving the plate would be $(V_i - 2\phi_-) = 21.5 - 8.8 = 12.7v$, where $V_i = 21.5v$ is the ionization potential for neon. Here $2\phi_-$ must be subtracted because the potential energy of the ion is used to liberate two electrons: one for neutralization of the ion and the secondary electron emitted from the plate. The value of the work function for nickel under the present conditions is not accurately known because the influence of adsorbed gas layers may change this appreciably. Van Voorhis¹³ found for molybdenum in a neon discharge $\phi_- = 3.68$, but the determination was made above the space potential so that the collector was receiving only electrons. In the present work it was found that the condition of the metal surface, when this is collecting electrons, may be somewhat different from that when bombarded with ions. The accuracy of this first method is not sufficient to decide between the two possible processes for the liberation of electrons mentioned above.

The form of the velocity distribution curve II (Fig. 2) does not change appreciably when the experimental conditions are varied. It seems to be practically independent of the plate voltage when this changes from $-75v$ to $-300v$. The maximum is rather sharp for low pressures and small distances of the cylinder from the plate. When the pressure is higher ($p = 5 \times 10^{-2}$ mm and more) or the distance d rather large the peak becomes less sharp; this is probably due to the impact suffered by the electrons on their path from plate to cylinder. At the same time the foot of the curve extends farther to the right, while a break appears in curve I (Fig. 2) at $(V_P)_a = (V_C)_a - 20$, (in the case of Fig. 2 at $(V_P)_a = -145v$). As may be seen from curve II of Fig. 2, which is a typical velocity distribution curve, there is no sharp maximum or minimum velocity as found by Oliphant¹¹ in his work on secondary emission by metastable He atoms. This may be partly due to a difference in the surface condition of the metal emitting the secondary electrons, but probably is mainly caused by scattering on their way from plate to cylinder. The maximum in the distribution curve corresponds always to a plate potential $(V_P)_a$ a couple of volts less negative than the potential of the cylinder. If the average velocity of the secondary electrons leaving the plate is a couple of volts, the velocity distribution curve will be of the form represented in Fig. 2.

¹³ Van Voorhis, recent unpublished work.

For a rational choice of the difference between the reference line AB and curve I of Fig. 2, representative of the secondary electron current collected by the cylinder, we must remember that, for a given value of the plate potential $(V_P)_a$, only those electrons reach the cylinder whose velocity normal to the space charge sheath corresponds to an energy equal to $(V_C)_a$. The loss of forward momentum of the part electrons coming from the plate is due to two effects: elastic scattering with change of direction of motion and inelastic impacts (excitation and ionization) with or without change in direction. The break in curve I (Fig. 2) referred to above may be due to excitation of neon, since the loss of energy corresponds roughly to 18 v.

To know the electron component of the plate current, i_p , we must extrapolate back the recorded electron currents, Δi_C . This requires a knowledge of the electron mean free path λ_- for the different velocities corresponding

Fig. 3. Plate potential $(V_P)_a = -125$ v. $I = 450$ ma. $V = 59$ v. Pressure 8.8 to 9.2×10^{-3} Hg. Curve I: Δi_C for $(V_C)_a = 10$ v. vs. d . Curve II: Δi_C for $(V_C)_a = 25$ v. vs. d . Curve III: i_p in each case. Curve IV: i_C vs. d .

to $(V_P)_a$. As a first approximation we may take the gas-kinetic value for λ_- which for neon is 0.0737 cm at 1 mm pressure. Since the collecting cylinder C could be moved with respect to the plate, a direct determination of the electron mean free path would seem possible. The cylinder potential $(V_C)_a$ was given a definite value -125 and the variation of Δi_C with distance d studied, all other conditions being kept constant as well as possible. The two upper curves in Fig. 3 give Δi_C for $(V_P)_a = (V_C)_a - 10$ (curve I) and $(V_P)_a = (V_C)_a - 25$ (curve II), both plotted at the same scale but shifted the one with respect to the other to avoid confusion. The curves do not show an exponential decrease as would correspond to the simple formula $N_d = N_0 e^{-d/\lambda}$. The maximum in the Δi_C curve between positions II and III of the cylinder is due to the disturbing effect of the latter when it comes too near to the plate. As will be shown later, the secondary emission from the plate is due partly

to ion impact and partly to impact of metastable atoms. The latter are constantly diffusing from the center of the tube towards the wall and the presence of the cylinder in front of the plate probably disturbs the concentration gradients and decreases the number of metastable atoms striking the plate in unit time. To a certain extent this must also be true for the positive ion currents, but to a much smaller degree because of the correcting effect of space charges. The part of the curves to the right of position IV can be used for the calculation of the electronic mean free path. Table I gives the results of these computations. The first row gives the distance d of the

cylinder from the plate, the second the electron currents at the cylinder (in $\mu A/cm^2$) for (V_P)_a = -135 v for different values of d . In the third are shown the values of the electron mean free path calculated from electron currents Δi_C for two adjacent positions. The fourth row gives the pressure in the tube for the different runs. (The small variation of the pressure shown in the table is due to the construction of the tube. The change in position of the cylinder influenced the rate of circulation of the gas in the tube and a readjustment of the pressure would have taken a rather long time. We thought it preferable to make all the runs in rapid succession to avoid a change in the discharge conditions, especially the purity of the gas.) The fifth line gives the gas-kinetic values for the electron mean free path corresponding to the pressures given in the fourth row. Most of our data have been taken with the cylinder in position IV, but much also in positions III and V. The sixth row of Table I gives the values of i_p^- calculated from those of Δi_C (second row) using the gas-kinetic mean free path for electrons (fifth row). The next row gives the total current to the plate i_p ($\mu A/cm^2$). On the last line are given the ratios of i_p^- to i_p (electron current to the total current) in percent of i_p called γ . In calculating values of i_p^- from the observed values of Δi_C , the gas kinetic values of λ were used in the exponential formula. Had the empirical values of row 3 been used, the values of i_p^- and hence of γ would have been still larger, except for positions III and IV in which there is the following geometrical complication. In the calculation of i_p^- from Δi_C the geometric arrangement of the apparatus must be taken into account. Part of the electrons colliding between plate and cylinder are scattered at small angles from their original direction and will still be collected. This effect will slow

down the decrease of the beam for positions of the cylinder near the plate. This may partly account for the large value of the electron mean free path obtained from the readings at positions III and IV.

The values for γ obtained from the different positions of the cylinder decrease when the distance d of cylinder to plate increases; this shows that the actual decrease of the electron current with distance is larger than would correspond to the exponential law $N = N_0 \exp(-x/\lambda)$ where λ is the gas kinetic value. Using the independent measurements obtained with the Faraday box (third method), it was found (under discharge conditions practically the same as in the case under consideration) that when the theoretical value for the electron mean free path is used in conjunction with the data obtained for Δi_C , at position IV, the value of i_{P^-} may be calculated quite accurately and consequently also that of γ . This would give in the present case a secondary emission of 24 percent. Even if we did not take into account the decrease of the secondary electron beam on its path from plate to cylinder, we would find, using the data of Table I, $\gamma = 17$ percent for position III and $\gamma = 16$ percent for position IV.

The values of γ obtained by the method outlined above vary within rather wide limits (15 to 50) according to the pressure and the degree of purity of the gas. In the runs which gave the data presented in Table I the neon contained slight traces of some impurity. The method under discussion does not permit a separation of the two effects which give rise to the secondary emission: impact of positive ions and impact of metastable atoms. The latter depending on the concentration of the metastable atoms in the discharge is likely to change considerably with the degree of purity of the gas. Table II gives some further illustrations. The values for γ at a given

For first seven $d = 4.34$ cm, for last five $d = 3.33$ cm. I = total current through tube in m.a. V = drop across tube in volts. p = pressure in mm of Hg. Currents in cols. 5, 6, 7 in $\mu A/cm.^2$

pressure could be reproduced very well, but it was always found that higher pressures give larger values for γ (for a pressure variation from 5×10^{-2} mm to 8×10^{-3} mm). This variation of γ is principally due to the dependence of the concentration of metastable atoms on the pressure in the discharge tube.

We also tried to find the variation of γ with the plate potential $(V_P)_a$, the accelerating potential for the positive ions. As may be seen no appreciable variation was found. It is well known that the number α of electrons liberated per positive ion increases with the velocity of the ions. But in our case the emission i_P^- which gives γ is made up of two parts: electrons due to ions and electrons due to metastable atoms. Only the first part would vary with the plate potential and this part only contributes to α , so that the variation of i_P^- with $(V_P)_a$ is smaller according to the degree of preponderance of metastable atoms over ions as emitting agents.

We have for the present no definite interpretation for the decrease of γ with increasing $(V_P)_a$, which is especially marked in the lower set of Table II, where γ varies from 38 to 31 percent for $(V_P)_a$ varying from -100 to -300 v. One possibility is that the ions in falling through the sheath destroy a certain number of the metastables on their way to the plate; the larger $(V_P)_a$, the thicker the space charge sheath becomes, and, consequently, the loss of metastables due to positive ion impact also increases. Another effect of the ion impacts in the sheath could be the production of new metastable atoms by impact between fast ions and normal atoms, with a maximum for this process in the neighborhood of the normal cathode fall in neon which is around 100 v. Another possible, though improbable explanation is destruction of metastable atoms by absorbed light (red) or by impurities while traversing the sheath.

An interesting conclusion can be drawn from the data presented in Table II. In the noble gases the volt-ampere characteristic of a negatively charged plane collector (with guard ring) does not present a saturation character⁸ as in the case of mercury vapor.⁹ This may be attributed in part to the increase in ionizing power of the secondary electrons caused by the increase in the accelerating potential acting on them as the plate potential is made more and more negative. In the lower set of data in Table II this increased ionization is shown by the fact that i_P^- remains almost constant while i_P increases with the change in plate potential from -100 to -300 v. A more general case occurs in the upper set of data of Table II, where both i_P^- and i_P increase with increasing negative plate potential, indicating both increased ionization and increased secondary emission.

Second Method. The second method involves the use of the same electrodes as does the first method. In this the plate voltage $(V_P)_a$ is kept constant while the voltage of the movable cylinder $(V_C)_a$ is varied. The positive ion current collected by the cylinder therefore changes, decreasing with decreasing negative voltage, (right to left on Fig. 3). As the voltage of the cylinder becomes more positive and goes through the fixed voltage of the plate at point C, the cylinder current, i_C , shows an additional decrease (curve I, Fig. 4, B to C) due to the reception from the plate of secondary electrons which have previously been turned back. In the run to which Fig. 4 refers, the plate voltage $(V_P)_a$ was -100 v with respect to the anode, and the cylinder voltage $(V_C)_a$ was changed from -125 to -90 . The part AB of curve I, where no electrons are received, is extended in the dotted line BB' which indicates the value of the positive ion current collected by the cylinder.

(Since only the variations in the current are plotted, an arbitrary zero point is selected for convenience at *E*). The differences, *e*, between the measured current and the extrapolated positive ion current are plotted as a function of the cylinder voltage in curve II, which has the same general shape as curve I of Fig. 2. This curve is reversed right for left as compared with that of the first method since the potential changes are made in an opposite manner.

As in the first method it is seen that the electrons may have as much as 12.5 volts initial energy since they are received even when the cylinder is 12.5 volts more negative than the plate. The method of obtaining the reference line *ABB'* of curve I precludes the possibility of discerning a gradual rise in *FG* of curve II corresponding to that found in some cases in the curves of the first method, e.g., *AB* of curve I of Fig. 2. Otherwise, however, the remarks made in connection with the first method apply here. The value of

Fig. 4. Curve I. Change in i_c in $\mu A/cm^2$ vs. $(V_c)_a$. Curve II. Difference e vs. $(V_c)_a$.

the initial secondary electron current i_P^- may be calculated by using the gas-kinetic mean free path. In the case illustrated, γ was 33 percent of the measured plate current.

The results of this method corroborate those of the first method, but, since the first method permitted the use of a more sensitive galvanometer, most of the runs were made with the first method. Table III gives some illustrative material.

TABLE III.

p	λ_{gk}	$(V_P)_a$	i_P	Δi_C	i_P^-	γ
2.4×10^{-2}	3.3	-80	219	18	67	31

p = pressure in mm of Hg. λ_{gk} = gas kinetic mean free path in cm. $(V_P)_a$ in volts. i_P , Δi_C , i_P^- in $\mu A/cm^2$. $\gamma = 100 i_P^- / i_P$.

Third Method. The first two methods are somewhat unsatisfactory, for in order to obtain quantitative data on the secondary emission some exponential decrease of the electron beam as it goes from the plate to the movable collector must be used. Since the appropriate value of the mean free path is not exactly known, there is some uncertainty in the results. Obviously, however, those methods give a lower limit to the secondary emission. The method now about to be described gives more definite information, which is free from the defect mentioned.

The movable cylinder *C* is not used and is drawn up out of the discharge. The plate (Fig. 1) has a hole at its center, behind which is the hole in the Faraday box *B*. The shield cylinder *M* attached to the plate *P* protects the box *B* from particles which may come through the annular slit *S* between the

Fig. 5. Box current i_B vs. $(V_B)_P$ for plate potentials $(V_P)_a = -75, -100, -125$ and -150 .

plate and its guard-ring *G*. The reason for this will be discussed later. The plate *P* is given some definite potential $(V_P)_a$, measured with respect to the anode, and the box *B* is made positive or negative with respect to the plate. The total currents to the box and to the plate are measured. Suppose, for example, that the plate is made negative, say -75 volts, so that there is a positive ion current to it. Some of the ions accelerated in the sheath will go through the hole in the plate and into the box *B* beneath when the potential between the box and the plate $(V_B)_P$ permits them. Fig. 5 gives plots of the box currents i_B against the box potential measured with respect to the plate $(V_B)_P$, for plate potentials of $(V_P)_a = -75, -100, -125$, and -150 volts. The curves are plotted on the same scale, but the zero points indicated by the short horizontal lines at the points *O* and *F* are displaced to avoid superposition.

The behavior of the current is much more complicated than one would anticipate under the assumption that the secondary currents are due to positive ions alone. One would expect, for instance, that as the retarding voltage of the box increases, the box current would be constant up to the potential of the space from which the ions have come, at which it would fall sharply to zero and remain so for increasing retarding potentials. A comparison of the magnitude of this current per unit area of the hole with the measured current per unit area of the plate would then give the proportion of the plate current carried by the positive ions alone, assuming that secondary electrons ejected by the ions inside the box B would have a very small chance of escaping from it. The curves of Fig. 5 indicate that a more detailed study is necessary. The break in the current at point F occurs at a retarding box voltage $(V_B)_P$ equal to that of the negative plate voltage $(V_P)_a$, indicating that most of the ions come from a space whose potential is nearly that of the anode. The final value of the current received on B for higher retarding voltages is not zero but a constant negative quantity (points H to I of the plot, Fig. 5). Furthermore the curve $ABCD$ shows a diminution in the current when the box is brought from a negative potential with respect to the plate to a positive one. The magnitude of this diminution for any set of experimental conditions is independent of the potential of P .

In one set of electrodes the inner shield cylinder M (Fig. 1) was omitted, and in this case the action of metastable atoms could be particularly easily demonstrated. Assume that the ions which come through the hole in the plate P go directly into the box B whenever the potential is favorable, and that metastable atoms, on the other hand, are diffusing from the discharge in a random direction through the hole in the plate and the annular slit S . When the inner shield cylinder M was absent, the metastable atoms which came through the hole and the slit S struck the box B on its outer surface and also the under side of the plate and guard ring, and the inside of the outer shield cylinder L . When the potential of the box $(V_B)_P$ was made more and more positive with respect to the plate, any electrons liberated by the action of the metastable atoms on the inner side of the plate or outer shield cylinder L came to B . This current was considerably greater than the positive ion current coming through the hole to the box, since the measured current was negative. A reversed field gave a large current in the opposite direction. Furthermore, it was found that a field across the slit had no effect on these currents between the box B and the outer cylinder L , which again indicates that they are caused by the neutral metastable atoms. To test this the inner shield cylinder M was introduced and fastened to the under side of the plate P so that the space within was shielded from whatever particles might come through the slit S . This is the case for which the curves of Fig. 5 are plotted. Now the relatively large currents above mentioned are practically absent. The current now does not become negative until after the positive ions are repelled at the point F of the curve. The only opening through which the metastable atoms can come is the hole through which the positive ions also come. Part of the former having, as we assume, a random direction, go into

the opening in the box B where electrons ejected will have a very small chance of escaping. A certain proportion, p , of the metastable atoms hit either the outside of the box B , or the inner surfaces of the plate P or the cylinder M , from which the electrons liberated are drawn to the box B to be measured as an incoming negative current. An additional complicating effect caused by the ions repelled at the point F will be discussed later.

A similar argument explains the change in the current at the points BCD of the curve (Fig. 5) where $(V_B)_P$ passes through zero. When $(V_B)_P$ is negative, electrons liberated from the box by metastable atoms striking it on its outer surfaces are drawn from it to the surrounding shield cylinder M and plate P , since the latter are more positive. This appears in the galvanometer as an incoming positive current along with the true positive ion current i^+ . This current i_1^- is stopped when the potential difference $(V_B)_P$ is sufficiently positive to counteract the initial velocities of the electrons, say 12.5 volts, corresponding to the value found by methods one and two. The difference in ordinate CD' , therefore, gives a measure of i_1^- . On the other hand, when $(V_B)_P$ is positive, a secondary current i_2^- in the reverse direction flows, caused by the reception at B of electrons liberated on the inner sides of P and M by the action of the metastable atoms which strike them. The measured positive current i_B is then smaller than i^+ since the reception of electrons is equivalent in the galvanometer to a failure to receive positive ions. If, however, $(V_B)_P$ is decreased through zero, this current is stopped by 12.5 volts corresponding again to the initial energies of the electrons. The difference in ordinate CB' is therefore a measure of i_2^- .

Thus the electrodes shown in Fig. 1 enable us to estimate separately the magnitudes of the secondary emission due to metastable atoms and to positive ions. If we assume, as seems necessary, that the efficiency of production of electrons by metastable atoms is the same at all of the surfaces concerned, then the sum of i_1^- and i_2^- , or $B'D$ on the graph, represents the effect of the proportion p of the metastable atoms coming through the hole. Assuming, however, that each unit area of the plate P is struck by as many metastable atoms as come through the hole per unit area, a value of the secondary electron current liberated from the surface of P by the metastable atoms can be obtained as shown in the following paragraph. The remainder of the secondary emission from the plate is then ascribable to the effect of the ions, thus giving a measure for α , the percentage yield of free secondary electrons for positive ions.

The measured current to the plate i_P , must now be separated into its component parts, that due to the true positive ion current i^+ and that to the secondary emission i^- . Assume that the line ED extrapolated to D' gives the correct value for the positive ion current due to positive ions of the voltage of the plate with respect to the space outside. (The slope of ED is probably due to the distortion of the field at the hole as the potential of the box is changed.) The ordinate OD' , however, must be increased by the amount of the secondary current i_2^- flowing from M and P to B when $(V_B)_P$ is positive. ($B'C$ on the curve.) This lowers the zero line to G' where $OG' = B'C$, giving

i^+ as $D'G'$. The zero line through G' when extended to the right intersects the curve at G and does not coincide with HI , as might be expected from the explanation previously given. That, however, was obviously incomplete since it neglected the effect of the positive ions repelled from the box when $(V_B)_P$ was more positive than $(V_P)_A$ was negative. Presumably these either go back through the hole or strike the plate on its under side, where secondary electrons are liberated and drawn to the outside of the box, giving the current i_3^- (GH' on the curve). The ratio of this current to the positive ion current gives a value for α (Table IV, column 5) independent of the effect of the metastable atoms. This enables us to calculate the proportion, p , of the number of metastable atoms which do not enter the opening of the box B (equal to 74 percent with the electrodes used). This value is of the order of that to be expected from the geometry of the hole and box. $B'D$ of the graph is then divided by p to obtain the equivalent effect i_m^- of the total number of metastable atoms which come through the hole in the plate. (Table IV). The measured plate current i_P is diminished by i^+ to obtain i^- , the total secondary emission. γ is the ratio of 100 i^- to i_P . The part i_i^- , of the emission due to positive ions is the difference between i^- and i_m^- . A second value of α can then be calculated by dividing 100 i_i^- by i^+ . (Table IV, column 10).

TABLE IV.

$(V_P)_A$	i_P	i^+	i_3^-	α	i^-	γ	i_m^-	i_i^-	α
-75	240	146	21	14	94	39	74	20	14
-100	248	150	24	16	98	40	74	24	16
-125	253	153	26	17	100	40	74	26	17
-150	260	154	30	20	106	41	74	32	20

$p = 2.0 \times 10^{-2}$ mm of Hg. Currents are reduced to $\mu A/cm^2$.

Assuming that the decrease of α with decreasing ion velocity is linear, the value of α_0 for ions of zero velocity is about 7 percent as given by the runs of Table IV.

The values of α are somewhat uncertain since the results depend on a very small variation in the deflection of a sensitive galvanometer. The consistency of the data is indicated by a comparison of columns 5 and 10 of Table IV and by four other runs at $(V_P)_A = -125$ volts for instance, which gave respectively $\alpha = 18, 17, 18$ and 17 . The last of these was taken with about twice as much total current through the discharge, so that i^+ and i_i^- increased in about the same proportion. The values of γ obtained by this method check well with those obtained by methods one and two, where the three methods were used in immediate succession. For example at $p = 1.3 \times 10^{-2}$ mm of Hg, γ was found to be 30, 31 and 33 by methods one, two and three respectively. This degree of corroboration was obtained throughout, indicating that values of γ found by the first two methods were a few percent too small.

Some comparisons of this work with that of other observers can be made. A variety of gases and metals have been used. The experimental conditions

were not similar in many cases to those used here where the circumstances arising at the cathode in a glow discharge were counterfeited as nearly as possible. In Penning's experiments^{4,5} the positive ions from the main discharge tube traversed a canal in an electrode and entered a more highly evacuated vessel wherein the target was located. The value of α_0 (2 to 10) which he finds is approximately that given here, but the rate of increase of α with voltage is less than that which we find (about 0.02 or 0.03 per volt for iron in neon and less than 0.01 per volt for copper in neon as compared with 0.08 per volt for nickel in neon.*)

Found¹⁴ reports values of the secondary emission from tungsten electrodes in neon larger than those obtained here. His method is to compare the measured current at various electrode potentials with the area of the sheath calculated by the equation given by Langmuir and Mott-Smith.⁹ He assumes that the true positive ion current is proportional to the area of the sheath, while the secondary electron is constant. The larger emission which he finds may be a consequence of a greater purity of the neon since impurities destroy metastable atoms, to which he ascribes the preponderant part of the emission. His calculations, however, neglect several points: the effect of the second order plasma fields on the variation of the positive ion current with voltage, the additional ionization due to the increasing ionizing power of secondary electrons accelerated by increasing potentials, and the increase of α with voltage.

VELOCITIES OF ELECTRONS FROM THE DISCHARGE

The perforated plate and Faraday box system was used with the potential of the plate in the neighborhood of the space potential to determine electron velocities. In the case illustrated by Fig. 6, the plate was put at -25 v, and the current to the box measured as the potential of the box with respect to the plate was changed. The electrons which came through the hole were finally repelled by a retarding potential of -30 volts. The residual current for higher retarding potentials was not zero but positive indicating either that positive ions were coming through the hole in small numbers or that an electron current was released from the box. The latter in view of the phenomena described under method three is extremely probable. In any case, when the current as measured from the zero of the galvanometer is increased by the amount of the residual positive current, the $\log i_B$ vs. $(V_B)_P$ plot gives a straight line over a considerable portion whereas the corresponding plot of the apparent current is not straight over any part. This indicates that these electrons have a Maxwellian distribution of velocities of which the average, in

* During the writing of this article a paper on this subject by Oliphant appeared. Proc. Roy. Soc. A127, 373 (1930). He finds in experiments with an apparatus somewhat similar to that of Penning (for molybdenum and helium) a linear increase of α with the voltage of the impinging ions (about 25 for 200 v to about 120 for 1000 v, or 0.105 increase per volt); but he shows that below 200 v α is almost constant. A smaller α (not linear) is found for heat-treated targets. The velocity distribution curves are similar to those reported here (almost all velocities less than 20 volts), but only the runs taken with heat-treated targets show kinks (cf. Fig. 2).

¹⁴ Found, Phys. Rev. 34, 1625 (1929).

the case illustrated, corresponds to 7.3 volts. This was corroborated by measurements using the plate P as a plane collector, according to Langmuir's method,⁹ which gave in the present case 7.7 volts. This sort of agreement was obtained throughout. The space potential, about -20 or -25 volts with respect to anode, as indicated by Langmuir's method for a plane collector, was not exactly the same as that given under method three, namely, about that of the anode; but obviously the conditions are not comparable, for in one case the collector—a rather large one—was drawing a large negative current, while in the other a large positive one. The distribution of current going to the various electrodes is materially different in the two cases.

Fig. 6. Curve I. i_B vs. $(V_B)_P$ for $(V_P)_a = -25$ v. Curve II. Uncorrected $\log i_B$ vs. $(V_B)_P$. Curve III. Corrected $\log i_B$ vs. $(V_B)_P$.

In all runs taken for $(V_P)_a$ between 0 and -15 volts there was a break downward in the $\log i_B$ vs. $(V_B)_P$ curve at $(V_B)_a = -21$ or -22 volts which indicates a deficiency of electrons of a voltage corresponding to the ionization potential of neon.

There is some evidence for the reflection of electrons from the plate when it is receiving a large negative current, for the current per unit area of the hole received at the box when $(V_B)_P = 0$ is much more than the current per unit area to the whole plate, for example 4970 as compared with 3750 $\mu A/cm^2$, or 25 percent reflection. This varied under different experimental conditions and for different voltages of the plate from about 5 to about 50 percent. Unfortunately the data on this point are at present not sufficient to say anything further.

The junior author is extending this work to other gases and discharge conditions. In conclusion we wish to thank Professor K. T. Compton for his aid and advice during the course of the experiments and in the interpretation of the data.

EXTINCTION OF SHORT A. C. ARCS BETWEEN
BRASS ELECTRODES

BY T. E. BROWNE, JR., AND F. C. TODD

RESEARCH LABORATORY, WESTINGHOUSE E. AND M. COMPANY*

(Received June 26, 1930)

ABSTRACT

Results are given which show that the dielectric recovery after current zero, of short, stationary A.C. arcs between brass electrodes, is similar to that of cold-electrode arcs previously investigated and described. These results also show that the rate of recovery of dielectric strength of hot-electrode arcs after a current zero may be greatly increased by reducing, within limits, the electrode separation. A possible explanation on the basis of ionic diffusion to the electrode surfaces and the deionizing action of blasts of metal vapor from the boiling electrodes is mentioned.

THE recovery of dielectric strength by an A.C. arc, immediately after a current zero at which it is extinguished, has been studied by Slepian¹ with the result shown in Fig. 1. The short arcs studied were kept in rapid

Fig. 1.

motion over copper surface terminals which are believed to have been cold. The ability to withstand about 230 volts was regained within less

* Scientific Paper No. 430.

¹ "Extinction of an A.C. Arc", J. Slepian, Trans. A.I.E.E. 47, 1398 (1928).

than a few micro-seconds after a current zero, and further dielectric strength was recovered thereafter at a much lower rate. The simple theory which Slepian gives identifies the quickly recovered dielectric strength with the minimum sparking potential or normal cathode drop in a glow in the gas next to the cathode. This should therefore be independent of current and of arc length. Slepian's theory also makes the slower further recovery of dielectric strength independent of current and arc length, but this part of his theory depends on the assumption that ions are lost from the arc space only by direct recombination. If other deionizing agents are not of negligible activity, such as for example, diffusion of ions into the electrodes, or diffusion into cooler surrounding gas with more rapid recombination there, then this slower later recovery should be influenced by arc length and current magnitude. The quickly recovered dielectric strength, however, should not be influenced by these other deionizing agents. Short stationary A. C. arcs in which the electrodes are hot might be expected to behave in a generally similar manner to the cold-electrode arcs which Slepian studied, provided that the boiling temperature of the electrode material is so low that appreciable thermionic emission is unlikely. Using stationary arcs with brass electrodes, the writers have conducted experiments which show that dielectric strength after current zero was recovered in the same manner as for the cold-electrode arcs of Slepian. The quickly recovered dielectric strength was independent of arc length, but the more slowly recovered dielectric strength varied with current and arc length, being greater for the smaller currents and shorter arc lengths.

APPARATUS AND METHOD

The circuit and the shape of the electrodes used in these tests are shown in Fig. 2. The source of power was a 100 KVA transformer bank with adjustable secondary voltage, whose primary was connected to a 2300-volt 60-cycle power line. The current was limited almost entirely by air-core reactors, having low power factor and comparatively low distributed capacitance. Following Slepian, the electrical transient of the circuit immediately after the extinction of the arc was controlled by shunting the arc electrodes with adjustable resistance made up of low-inductance wire-wound resistor tubes. To obtain the equivalent of exactly zero power factor in spite of resistance drops and arc voltage, a synchronous shorting switch was used to close the circuit at such a point on the voltage wave that the end of the first half-cycle of current occurred at the maximum of the sinusoidal generated voltage. An arc was formed almost immediately at the center of the electrodes by the burning of a fine (No. 40 B. & S.) copper fuse wire, and the ensuing number of half-cycles of arcing was counted by means of a direct-vision oscillograph. When the arc shunting resistance was high the arc would continue for many half-cycles; when the shunting resistance was low the arc would extinguish at the end of the first half-cycle. The resistance shunt was varied between trials until the value that would just cause the arc to go out at the end of the first half-cycle was determined within 5%. During a

short time after a current zero at which the arc is extinguished the voltage across the gap is approximately given by the formula:

$$e = E_m(1 - e^{-Rt/L}) \quad (1)$$

where E_m is the maximum of the generated voltage, R , the arc shunting resistance, and L , the inductance of the circuit. L was determined from the r.m.s. short-circuit current I by the relation:

$$E_m = 2^{1/2} \cdot 2\pi \cdot 60LI. \quad (2)$$

When the value of R is small, and the arc is extinguished at the first current zero, the impressed voltage given by (1) remains below the recovered dielectric strength of the arc space. When the value of R is large, and the

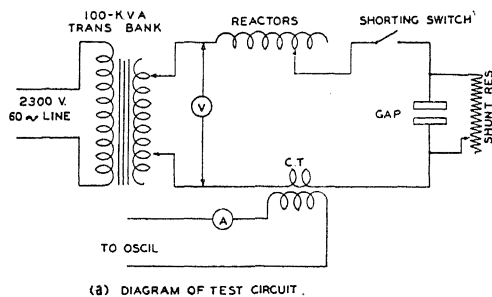

Fig. 2.

arc re-ignites, the curve of (1) will rise above the recovered dielectric strength of the arc space. For the critical value of R which just causes the arc to be extinguished at the first current zero, the curve of (1) must come up and just be tangent to the curve of the recovered dielectric strength of the arc space. By plotting a family of curves with different E_m 's, and corresponding critical R 's, the curve for the recovery of dielectric strength with time may be found by taking the envelope. No account is taken of distributed capacitance of the reactors and other parts of the circuit. Though these capacitances are comparatively small, they become appreciable when the critical value of resistance is high, and particularly when the shunt is removed altogether. The transient voltage will then generally rise in an oscillatory manner, reaching almost double the normal peak value. For this reason, tests in which nearly full voltage is recovered in less than ten micro-seconds are inaccurate and of value only for comparative purposes. Roughness of and

oxide formation on the electrodes after continued arcing may also cause considerable variation in results.

EXPERIMENTAL RESULTS

The curves of Fig. 3, which show results obtained for 1.6 and 3.2 millimeter arcs of 300 amperes, are similar in shape to curves obtained for cold-electrode arcs (Fig. 1). From these curves we see that the immediately

Fig. 3.

recovered ability to stand voltage is the same for the two arc lengths, but that after that the shorter arc recovers dielectric strength faster than the longer arc. Thus we are led to the interesting and at first sight paradoxical fact that a very short arc may be extinguished more easily than a longer arc.

Fig. 4.

This influence of arc length on recovered dielectric strength was found to continue up to lengths of 5 cm and more, by tests on 300-ampere arcs in a 450-volt (r.m.s.) circuit. The critical shunting resistance for arc extinction was determined for different arc lengths, and the initial rate of rise of voltage for the transient corresponding to each critical resistance was computed. The results are shown plotted against arc length in Fig. 4. It is noticeable that the factor causing this variation with gap length is most effective as the electrode separation becomes less than one centimeter. As this factor is undoubtedly a

deionizing one, and is probably active during the arcing period as well as during the extinction transient, we might expect it to reveal itself in the magnitude of the arc voltage. Figure 5 shows the variation of arc voltage with gap length. The definite increase in slope for the smaller lengths affirms the presence, even while the arc current is flowing, of some deionizing action which is more effective for short arcs than for long.

Fig. 5.

Figure 6 shows the results of tests at the same voltage and gap length but with currents ranging from 25 to 800 amperes. There is an undoubted decreasing tendency of these rather scattered values with increasing current.

Fig. 6.

According to the approximate theory of Slepian for the dielectric recovery upon extinction of a short A. C. arc, all of the regained dielectric strength resides in a positive space sheath next to the cathode. Due to the high mobility of the electrons, this space charge sheath is formed with extreme rapidity upon application of voltage and is immediately able to withstand a minimum of two or three hundred volts, depending only on the electrode material and the gas medium. Further recovery of dielectric strength results from increase in thickness of this space charge sheath due both to growth of applied voltage and to the diminishing density of ionization next to the cathode.

In Slepian's theory the loss of ions was assumed to be due solely to direct recombination in the arc space. The results given here confirm the fundamental conception of the formation and growth of a cathode space charge sheath, but the large influence of electrode separation points to the presence of some deionizing agent other than direct recombination which becomes rapidly more effective as the arc length diminishes. Since diffusion of ions into the electrodes is a process fitting this description, approximate calculations were made to determine to what extent this can account for the observed results. So far, however, the simplified calculations, assuming all of the deionization to be due to diffusion alone, and neglecting such influences as the electric field, vapor emission from the electrodes, and diffusion to the surrounding air, seem to require a coefficient of diffusion far in excess of any reasonable value. This may indicate that diffusion to the electrodes is an unimportant factor, or it may simply mean that the present approximate method of calculation is unsound. It is also thought possible that other physical processes may enter considerably into the deionization of the arc space next to the cathode, such as for example, a blast of metal vapor from the violently boiling electrodes during the arcing period and perhaps for a very short time immediately thereafter, but this theory lacks verification as yet. Therefore, further work is being done in an effort to arrive at a more nearly satisfactory explanation of these results.

RESTRIKING OF SHORT A. C. ARCS

BY F. C. TODD AND T. E. BROWNE, JR.

RESEARCH LABORATORY, WESTINGHOUSE E. AND M. CO.*

(Received June 26, 1930)

ABSTRACT

The restriking after zero current of short stationary A.C. arcs with brass, copper, zinc, iron, tungsten and carbon electrodes, and of arcs moving rapidly over copper electrodes was investigated with a cathode-ray tube of the Braun type. The volt-ampere traces on the fluorescent screen showed clearly the voltage necessary to restrike the arc after current zero, and the effect of the electrode vapor on the magnitude and variation of the restriking voltage. The arcs with refractory electrodes, i.e. carbon and tungsten, showed traces differing from the arcs with the other metals in that no high voltage for restriking the arc appeared. This is believed to be due to the refractory electrodes being at a temperature high enough for thermionic emission. For the other electrode materials, re-ignition voltages of several hundred volts were observed, suggesting that re-ignition of the arc required breakdown of a gas layer by ionization by collision alone. The arcs which were rapidly moving over their electrodes usually restruck to a glow before breaking down to an arc. The magnitudes of the restriking voltage and the glow current depended upon the condition of the electrodes, magnitude of the driving magnetic field, and the transient characteristic of the circuit in which the arc was playing.

IT IS well known that although a carbon arc can be maintained in a low voltage A.C. circuit, in general, an A.C. arc with metallic electrodes cannot be maintained with less than a few hundred volts. This has been studied by means of volt-ampere traces on the fluorescent screen of a cathode-ray tube of the Braun type, developed by Zworykin for use in television. These investigations have brought out several interesting facts about the magnitude of the voltage required to restrike the arc, and the manner of breakdown.

Slepian¹ has attributed this peculiarity of arcs mentioned, to the formation immediately after current zero of a thin deionized layer of gas next to the cathode. With thermionic emission lacking, to re-ignite the arc this layer would need to be broken down by ionization by collision and would require several hundred volts. His theory is illustrated by Fig. 1 which is taken from the paper referred to above. Starting with a uniform distribution of ions when the current and voltage are zero, the increasing voltage will cause space charge sheaths to form next to the electrodes after the manner described by Langmuir in relation to probe electrodes in an ionized gas. Because the mobility of the electrons is much greater than that of the positive ions, most of the applied voltage will be across the space charge sheath at the cathode. The current densities in this sheath are very small and in order to

* Scientific Paper No. 431.

¹ "Extinction of an A.C. Arc," by J. Slepian, Journal of the A.I.E.E. October, 1928.

restrike the arc, the space charge sheath must be broken down. If there are no other ionizing agents, the breakdown must be by ionization by collision only, and is entirely similar to the breakdown of a short spark gap. It will, therefore, require a minimum of several hundred volts. If, however, there are other ionizing agents, breakdown will occur at a lower voltage.

(a) DISTRIBUTION OF IONS IN GAS

(b) POTENTIAL DISTRIBUTION IN GAS

Fig. 1.

It seems unlikely that the temperature of the electrodes can be raised much above the boiling point. Hence, for non-refractory metals, i.e. zinc brass, copper, and iron, thermionic emission is probably entirely negligible. Hence, for these metals, the space charge sheath must be broken down by ionization by collision only. But carbon and tungsten at their boiling points

Fig. 2.

Fig. 3.

are at temperatures high enough for thermionic emission. Accordingly, for these electrode materials, we may expect breakdown of the sheath at low voltages. This occurs as is shown by the photographs of the dynamic volt-ampere characteristic on the fluorescent screen of the Braun tube. The photographs in Fig. 2 and 3 are for the carbon and tungsten arc respectively.

Fig. 4 shows the interpretation of Fig. 2 in the more familiar current and voltage against time relation. In Figs. 2 and 3 the current and voltage deflections are purposely not exactly in phase with the actual current and voltage and give the double line near current zero. The exposure for these photographs was 15 seconds, or included 900 retracings of the phenomenon.

Fig. 4.

Returning now to the non-refractory metals, we shall expect to see much higher breakdown voltages, and since the space charge sheath is composed chiefly of the metal vapor, the breakdown voltages required for the various metals will in general be different. This is illustrated by Figs. 5, 6, 7, and 8 which give a portion of the dynamic volt-ampere characteristics near the reversal of current for zinc, copper, brass, and iron respectively. The current

Fig. 5.

Fig. 6.

and voltage deflections are again not in phase with the actual current and voltage for Figs. 5 and 6, this displacement is to show the voltage before current zero as well as the restriking voltage. For the zinc arc, the restriking voltage is 280 volts and the voltage does not rise above arc voltage at the end of the half cycle. The stationary arc on copper has a peak restriking voltage of 360 volts, and the voltage before current zero rises to 280 volts.

The maximum restriking voltage for brass and iron were 255 and 290 volts respectively.

Fluctuations in the density of the breakdown voltage line indicates that reignition frequently occurred at low voltages in these stationary arcs. This requires some other ionizing agent than ionization by collision. What this

Fig. 7.

Fig. 8.

is is uncertain. Slepian suggests that the charging current to a particle or droplet making or breaking contacts with the cathode may cause a tiny spark which will make the space charge sheath collapse.

It is possible to cause an arc to move so rapidly over a clean smooth surface by means of a magnetic field that melting of the electrodes is prevented.

Fig. 9.

It is believed that the terminals of such an arc may be cold. The dynamic volt-ampere characteristic of such an arc is shown in Fig. 9. The maximum restriking voltage is 535 volts, the hesitation during the breakdown is at 325 volts. Fig. 10 is the interpretation of Fig. 9 in the more familiar relations, the scale is much expanded near the ends of the half-cycles for clearness. As

the impressed voltage increases by an oscillation at the natural period of the circuit, and as the density of ionization decreases due to recombination and discharging of ions into the electrodes, the thickness of the cathode space charge sheath increases. At peak value, the voltage across the sheath has exceeded the recovered dielectric strength, and the short gap breaks down by ionization by collision. The voltage drops from peak value to that of the

Fig. 10.

glow or occasionally even to arc voltage. The glow appears and remains a stable discharge until enough energy is put into the space adjacent to the cathode to give the conditions required by the cold electrode arc, then the transition from glow to arc abruptly occurs. The maximum glow current observed before transition to an arc was 4 amperes, and in this case meant that the glow was stable for longer than 10^{-4} seconds. The probability of a

Fig. 11.

glow occurring seems to be less for the higher restriking voltage. It also appeared that the magnitude of the current to which the glow continued, and the probability of a glow occurring at all both increase as the electrode surfaces which had been initially cleaned with emery become oxidized. Slepian²

² "Theory of the Deion Circuit Breaker", J. Slepian Journal of the A.I.E.E., Feb., 1929.

had predicted that re-ignition of the cold electrode arc takes place first as a glow and his expectation is here confirmed.

Another dynamic volt-ampere characteristic similar to Fig. 9 is shown in Fig. 11, the only difference is that the driving magnetic field was 16 series turns for the former as compared to 660 series turns for the latter. The maximum restriking voltage in Fig. 11 is 1065 volts as compared to 535 volts for Fig. 9. In each case the glow occurs at 325 volts. This high restriking voltage can be obtained with the weaker field by shunting the arc with a resistance to slow down the rate of increase of voltage after current zero. This is due to the longer time the deionizing processes are active and the resulting thicker deionized layer requiring more voltage to breakdown.

Fig. 12.

If an arc of approximately 90 amperes is drawn between plane electrodes with a fine fuse wire, generally the arc will not continue for several half-cycles where it was drawn but will wander about over the electrode surface. Judging by the trail, the arc does not move much while the current is flowing but restrikes after current zero to a position on one side of the position of the arc during the previous half-cycle. When moving in this manner tungsten and carbon arcs show a variable restriking voltage which may be quite comparable to that of non-refractory metals. The only metals among those tested which did not show this wandering behavior were zinc and to a certain extent brass. Copper arcs have a very peculiar volt-ampere characteristic while wandering as shown by Fig. 12. The hesitation at the peak of the restriking voltage varies from a minimum of about 250 volts to a maximum of about 325 volts.

THE PHOTOELECTRIC BEHAVIOR OF SOLID AND LIQUID MERCURY

BY DUANE ROLLER
UNIVERSITY OF OKLAHOMA

(Received June 26, 1930)

ABSTRACT

With monochromatic light, the photoelectric threshold wave-length for solid mercury, freshly distilled and frozen in vacuum, was $2750 \pm 25\text{\AA}$ for all temperatures between -190°C and the melting point. For room temperature it was $2735 \pm 10\text{\AA}$, confirming Kazda's value.

The photoelectric current excited by each of the lines 2537 \AA , 2653 \AA and 2700 \AA was independent of temperature between -190°C and *ca.* -125°C . Between *ca.* -125°C and -39°C there was a gradual small decrease in the current with increasing temperature, but this was not reproducible at definite temperatures and is attributed mostly to contamination and other secondary causes. With the possible exception of this decrease in current, there was no indication of an allotropic change in the mercury between -190°C and the melting point. The photoelectric current for the solid phase was always higher than that for the liquid at room temperature, possibly due to a change in the optical absorptivity of mercury with change in phase. Between -39°C and 0°C the emission curves show so much hysteresis that conclusions regarding this region are impossible.

THE photoelectric threshold for mercury at room temperature has been established at $\lambda_0 = 2735\text{\AA}$ by Kazda, Dunn and Hales.¹ Mercury at the melting point was investigated by Pohl and Gudden.² They were unable to detect any change in the threshold with melting but terminated their work with the conclusion that mercury is not a suitable metal for studying variations in the photoelectric effect at transition and melting points because of the difficulties inherent in such experiments at low temperatures. Recently, Margarete Grutzmann³ published a study of the photoelectric emission from mercury at low temperatures. No variation of the total emission with temperature was found and there was no change in the total emission at the melting point. Since monochromatic light was not used, it is impossible to interpret these results or to establish the behavior of the threshold.

The purposes of the present work with mercury were: (1) to find the effects of temperature and of changes in the state of aggregation on the photoelectric threshold and on the current excited by incident monochromatic light; (2) to check independently the value of the threshold at room temperature; (3) to seek evidence of a photoelectric nature regarding an allotropic change in mercury in the region between -190°C and the melting point. McKeehan and Cioffi⁴ determined the crystal structure of mercury

⁴ McKeehan and Cioffi, Phys. Rev. 19, 444 (1922).

at -115°C and Alsen and Aminoff⁵ determined the structure at -78°C . The two results are very different and thus point to the existence of an allotropic modification of the mercury occurring somewhere between -115°C and -78°C .⁶ On the other hand, Lark-Horovitz⁷ has recently found that the crystal structure of mercury at the temperature of liquid air is identical with that at the temperature of a carbon dioxid-alcohol mixture.

The apparatus for the present work, Fig. 1, was made of Pyrex glass and had no cemented joints or stopcocks in the high-vacuum system. Light from a mercury arc, which had been carefully calibrated⁸ and which was operated with constant voltage, current and temperature, passed through a Hilger quartz monochromator and a quartz lens into the quartz window of the photoelectric cell, and then through a slit in the anode onto the bottom of the cell. The anode was a circular disk of tungsten 3 cm in diameter, welded with nickel to a heavy tungsten wire which lead out through a horizontal tube 12 cm long to a Dolazalek electrometer of sensitivity 1100 mm

Fig. 1. Diagram of apparatus.

per volt at 1.5 m scale distance. The cell was shielded electrostatically by covering its outside walls with a paste made of powdered graphite, water, and a little water glass. When the cell was baked the graphite formed a hard conducting layer. Water glass, when used sparingly, apparently will not weaken Pyrex appreciably, for the cell was used for two months without breakage.

The mercury used as the cathode of the cell was cleaned and distilled by a special method⁹ and was then placed in the still, Fig. 1, where it was distilled repeatedly in high vacuum to remove occluded gases. Some of the mercury was then allowed to pass through a magnetically operated valve, Fig. 1, into the bottom of the cell, where it rested on the glass, but was in

contact with a tungsten wire kept usually at a potential of 20 volts negative to ground.

The cooling of the mercury was accomplished variously with liquid air, liquid air and alcohol, solid carbon dioxide, and solid carbon dioxide and ether, contained in a specially designed Dewar flask which surrounded the cell up, to a point 7 cm above the surface of the mercury cathode. Temperatures were measured with a constantan-steel thermocouple, enclosed in a glass tube and immersed in the mercury. To retard the collection of moisture on the cold cell, a current of washed and dried air was played continuously on the window and walls. The points where the tungsten leads emerged from the cell were kept dry by means of small heating coils and drying materials. Surrounding the cell was a double-walled galvanized iron box, lined with asbestos, which helped to keep out moisture and which also served as an oven for baking the cell and as an additional electrostatic shield.

With the cell of Fig. 1 the threshold for mercury at room temperature was found to be at $2735 \pm 10A$, in agreement with the results of previous workers.¹⁰ This constitutes an independent check of the previous work, both because the mercury was here in contact with glass and tungsten, rather

Fig. 2. Diagram of modified apparatus.

than iron, and because the cell involved relatively few metal parts and probably was more thoroughly outgassed than the cells previously used.

When it was attempted to use this cell for low temperature work several defects in its design became apparent and this led to the construction of a new cell, Fig. 2, which differed from the old one in the following respects. (a) A second quartz window was cemented to the cell at a point considerably above the region to be cooled, the space between the two windows being evacuated. This gave improved thermal insulation and also made it possible to dispense with the current of air on the cell. Compressed air usually contains oil which forms a film on the window; no simple way could be found for removing all the oil from the air. (b) The anode, including the lead through the glass wall of the cell, was cut out of a single sheet of tungsten. In the old cell, the anode consisted of a tungsten sheet welded to tungsten wire and it was the seat of thermoelectric forces which produced erratic effects during times that the temperature of the cell was changing. (c) An iron cup 2.5 cm in diameter served as a container for the mercury cathode, the size of this cup being such that light fell only on the central unstrained part of the frozen

¹⁰ Reference 1.

mercury. The mercury was admitted to the cup through an iron tube, so arranged that it did not need to pass through the glass wall of the cell. In the old cell the mercury ran in over the glass, resulting in the formation of electrostatic charges which would persist for as much as an hour. (d) The mercury pump attached to the cell was enlarged so that it could be immersed in liquid air, thus retarding the condensation of mercury vapor on the surface of the solid mercury cathode. Preliminary experiments had shown that without this protection enough mercury condensed on the surface of the empty iron cup, when the latter was cooled, to produce an appreciable photoelectric current. Experiments made very recently at the University of Oklahoma by Mr. Carl Woodward and the writer indicate that a thin film of frozen mercury deposited on iron has both a high photoelectric sensitivity and a threshold wave-length longer than 2735Å. In view of these results, it might be advisable to seal off the photoelectric cell from the pumps and mercury still before attempting to determine the threshold of solid mercury.

In order to determine the thresholds at various temperatures, measurements were made of the photoelectric current at a particular temperature as a function of wave-length. Thresholds were then determined in the usual way by plotting the current excited by unit intensity of the incident light as a function of wave-length.¹¹ In the region -190° to the melting point, the threshold was established at $2750 \pm 25\text{Å}$, independently of the temperature. Thus, within the experimental error, the threshold for solid mercury is the same as that for liquid mercury at room temperature. When the solid mercury was held at low temperatures for times exceeding about one hour, the threshold began to shift slowly to shorter wave-lengths. There was ample evidence that this shift was due to contamination.

Measurements were also made of the photoelectric current for a given line as a function of temperature. Results typical of sixty curves made for the lines 2537Å, 2653Å, and 2700 Å are shown in Fig. 3. The arrows indicate the direction of temperature variation. The time required to obtain data for a given curve varied between 30 minutes and 12 hours, depending upon the method of cooling and the number of observations made.

Fig. 3 shows that the sensitivity of the mercury to monochromatic light was practically independent of temperature in the region -190° to *ca.* -125° . Between the latter temperature and the melting point, -39°C , slight changes occur in the slopes of the sensitivity curves but these could not be reproduced at definite temperatures. They were found to be associated closely with changes in the level of the cooling agent surrounding the cell and with abrupt changes in the rate of warming and cooling. Experiments showed that contamination released from the walls of the cell lowered the sensitivity of the mercury. Abrupt changes in temperature had a marked effect on the appearance of the solid mercury surface, particularly when the mercury was near the melting point; thus it is very likely that such abrupt changes of temperature also affected the photoelectric efficiency of the mercury surface.

Nothing was observed in the region between -190° and -39°C that could be attributed to an allotropic change in the mercury. This excepts

¹¹ R. A. Millikan, *Phys. Rev.* 7, 380 (1916).

the slight decreases in sensitivity which always accompanied rises in temperature and which have been at least partly accounted for in other ways.

During melting and freezing the sensitivity of the mercury changed rapidly. In the region between -39° and 0° C the liquid mercury showed great susceptibility to some unknown contamination which lowered the sensitivity. The curves, Fig. 3, show so much hysteresis in this region that no conclusions can be made as to the effect of temperature on the liquid mercury. The contamination was of such a kind that it could be eliminated immediately from the mercury surface by heating the cell a few degrees above room temperature.

It is to be noted that the sensitivity of the solid mercury always was higher than that of the liquid at room temperature. Since the thresholds

Fig. 3. Photoelectric current for lines 2537A, 2653A and 2700A as a function of temperature.

were found to be the same in the two cases, the higher sensitivity of the solid must be attributed to a change in the photoelectric efficiency of the mercury surface with change of state. This change in efficiency may be due to a change in the optical reflectivity of mercury with change of state. No exact information is at present available regarding the reflectivity of a very pure solid mercury surface formed in high vacuum although experiments are in progress. Haak and Sissingh¹² found no change in the optical constants of mercury either on freezing or in subsequent cooling down to -80° C, but the mercury surfaces used by them contained adsorbed layers of air.

This work was done in 1928 at the Norman Bridge Laboratory of Physics, California Institute.

It is a pleasure to acknowledge my indebtedness to Professor Millikan whose interest and guidance prompted the choice of subject and made the work possible.

THE THERMODYNAMIC TREATMENT OF CHEMICAL EQUILIBRIA IN SYSTEMS COMPOSED OF REAL GASES. I.
AN APPROXIMATE EQUATION FOR THE
MASS ACTION FUNCTION APPLIED
TO THE EXISTING DATA ON
THE HABER EQUILIBRIUM

BY LOUIS J. GILLESPIE AND JAMES A. BEATTIE

RESEARCH LABORATORY OF PHYSICAL CHEMISTRY, MASSACHUSETTS INSTITUTE OF TECHNOLOGY*

(Received June 30, 1930)

ABSTRACT

All of the equilibrium data on the ammonia synthesis reaction, which cover an extreme temperature range of from 325° to 952°C and an extreme pressure range (at some temperatures) of from 10 to 1000 atmospheres, are correlated with the compressibility and heat capacity data on the pure reacting gases by means of a rational and relatively simple equation for the mass action function K_p . In this equation the effect of temperature and of pressure on K_p are separated, the relation for the temperature effect being exact, but certain approximations being introduced for the sake of simplicity into the relation for the pressure effect.

All of the data on the ammonia synthesis equilibrium are represented within the experimental accuracy by the use of only two adjustable constants.

1. INTRODUCTION

THE use of high pressures in industrial chemical operations has disclosed numerous cases in which the deviations from the laws of ideal gases are of practical importance. We may mention the following two groups of phenomena:

1. When a vapor is condensed out of a gaseous mixture, more of the vapor has been found to remain uncondensed than would be expected from the laws of ideal gases. Typical cases¹ are the removal of ammonia from mixtures containing hydrogen and nitrogen, of carbon monoxide from water gas in the industrial preparation of hydrogen, and of nitrogen from nitrogen-hydrogen mixtures. The phenomenon has been studied by Pollitzer and Strebel,¹ Larson and Black,² Lurie and Gillespie,³ McHaffie,⁴ Eucken and Bresler,⁵ and Braune and Strassmann.⁶

2. In the fixation of nitrogen by the Haber process, the reaction for which is

there is a greater yield of ammonia as the pressure is increased than that calculated from the laws of ideal gases.^{7,8}

The deviations in these two classes of phenomena are due to the same cause, the failure of the ideal gas laws, and the explanation of one of these will furnish the basis for an understanding of the other. In the present paper we are interested in testing an improvement on the ideal-gas mass action law by the use of the existing data on the equilibrium of the chemical reaction given in Eq. (1).

Much of the interest in the mass action law has been confined to the case of solutions of electrolytes. In this laboratory, however, Keyes⁹ has for some years been collecting and correlating the compressibility data on gases in realization of their importance to chemistry in connection with the mass action law.

The thermodynamic connection between the mass action law and the pressure-volume-temperature relations for pure gases and gas mixtures has been given,¹⁰ the general relation being:

$$RT \ln (K_p/K_p^*) = - \sum \left\{ \nu_i \int_0^p [(dV/dn_i)_{T,p,n} - RT/p] dp \right\} \quad (2)$$

in which K_p is the "equilibrium constant" at the pressure p , and is defined by the relation:

$$\ln K_p = \sum (\nu_i \ln p x_i) \quad (3)$$

and K_p^* is the limiting value of K_p as the pressure on any mixture maintained in equilibrium is isothermally decreased to zero. The quantity ν_i is the coefficient of the substance i in the chemical equation for the given reaction and is negative if the substance disappears; x_i the mole fraction of substance i in the equilibrium mixture; and $(dV/dn_i)_{T,p,n}$ the partial molal volume of gas i in the mixture. A relation¹¹ for K_p in terms of the independent variables V and T is:

$$RT \ln (K_p/K_p^*) = \sum (\nu_i) RT \ln \frac{pV}{\sum (n_i) RT} - \sum \left\{ \nu_i \int_V^\infty [(dp/dn_i)_{V,T,n} - RT/V] dV \right\} \quad (4)$$

wherein K_p^* is related to the temperature by the relation:

$$\ln K_p^* = \sum (\nu_i) (\ln T/T_0 - 1) - \frac{1}{RT} \sum \left\{ \nu_i \left[\int_{T_0}^T C_{V,i}^* dT - T \int_{T_0}^T \frac{C_{V,i}^*}{T} dT + u'_{0i} - Ts'_{0i} \right] \right\} \quad (5)$$

in which $C_{V,i}^*$ is the heat capacity at constant volume for gas i at zero pressure, and u'_{0i} and s'_{0i} are constants for gas i . These relations depend upon two assumptions¹² and the general laws of thermodynamics.

We may evaluate the partial derivatives of equations (2) or (4) graphically, by approximate methods, or from an equation of state of mixtures.

It has been shown¹⁰ that if the Lewis and Randall rule¹³ for calculating the fugacity of a gas in a mixture holds, then the partial derivative of Eq. (2) may be replaced by the molal volume of the pure gas at the temperature and pressure of the mixture, and Eq. (2) reduces to the simple, approximate relation:

$$RT \ln (K_p/K_p^*) = \sum \left\{ \nu_i \int_0^p [(RT/p) - (V_i/n_i)] dp \right\} \quad (6)$$

The differences between the molal volume and the partial molal volume have been studied for several mixtures.¹⁴ A further approximation of (6) is obtained by assuming the integrand constant during the integration and equal to its limiting value at zero pressure, which can be calculated from an equation of state for mixtures. The equation is^{10,15}

$$RT \ln (K_p/K_p^*) = - \sum \{ \nu_i (B_{0i} - A_{0i}/RT - c_i/T^3) \} p \quad (7)$$

where R is the ideal gas constant and B_{0i} , A_{0i} and c_i are equation of state constants for gas i .

Keyes¹⁶ has given an equation for the mass action function K_p for gases whose isometrics are linear by use of the kinetic considerations from which the Keyes equation of state was derived.⁹ Application of this equation to the Haber equilibrium data showed a tolerable agreement up to 600 atmospheres.

Gibson and Sosnick¹⁷ and Merz and Whittaker¹⁸ have calculated the fugacity of a gas in a mixture by graphic methods. In order to carry out the computation it is necessary to make some assumption regarding the expansion of gases on mixing at infinitely low pressures. They assumed this to be zero but this assumption is not supported¹⁴ by the experimental data.

Van der Waals hoped to determine an equation of state for gas mixtures from the equations of state of the gas constituents together with two

adjustable constants, characteristic of every binary combination of constituents, the so-called interaction constants. Various methods for calculating these interaction constants from the values of the corresponding constants for the pure gases have been suggested. Keyes, working with an equation of state⁹ better adapted to representation of the compressibilities of the pure gases, found that a very simple method of calculating the interaction constants sufficed for the representation of the pressures of mixtures of methane and nitrogen measured by Keyes and Burks.¹⁹ Lurie and Gillespie³ were successful with the same method in accounting for their measurements of the effect of nitrogen on the vapor pressure of the system: barium chloride, barium chloride octamine. The necessary parameters for the gas mixture are calculated by a simple scheme, which may be designated as linear combination of constants:

$$k_x = k_1x_1 + k_2x_2 + \cdots = \Sigma(k_ix_i) \quad (8)$$

where k_x represents the parameter for the mixture and k_1, k_2, \cdots , represent the corresponding constants for the pure gases. All the constants for pure gases are dimensionally of the first power in the volume, except the cohesive pressure constant A , which is of the square of the volume. The linear combination rule is applied as above to the square root of the cohesive pressure constant, and directly to the others. A fuller discussion of the work of earlier investigators on the calculation of interaction constants is given elsewhere.²⁰ By means of this linear combination of constants we are able to calculate the values of the parameters for a mixture when the composition of the mixture and the constants of the pure gases are known, without the introduction of arbitrary constants.

In a series of investigations from this laboratory^{14,20,21} it has been found that when this scheme is applied in connection with the Beattie-Bridgeman equation of state²² the pressure-volume-temperature data on mixtures are represented very well, possibly within the experimental error. For chemical purposes it appears that a much smaller degree of success would suffice, as evidenced by the success obtained¹⁰ in representing the Haber equilibrium data to 100 atmospheres by the use of Eqs. (6) or (7).

Eq. (4) can be integrated¹¹ in terms of elementary functions by use of the Beattie-Bridgeman equation of state for mixtures. The equilibrium constant is expressed in terms of the temperature and the volume of the equilibrium mixture. This latter quantity must be computed from the equation of state, since the data are always given in terms of pressure and temperature, and hence an expression in terms of these latter variables is desirable. Eq. (2) gives such an expression, but the integration cannot be carried out in terms of elementary functions of the pressure and temperature from any of the usual equations of state.

II. A SIMPLE MASS ACTION EQUATION

A simple form of the mass action equation, explicit in the pressure, has been obtained¹⁵ by approximate integration of Eq. (2), and evidence given that this equation should furnish a very good approximation. The equation is

$$\ln K_p = \ln K_p^* - \left\{ \sum [\nu_i (B_{0i} - A_{0i}/RT - c_i/T^3)] + \sum [\nu_i (A^{1/2}_{0i} - \sum x_i A^{1/2}_{0i})^2/RT] \right\} p/RT \quad (9)$$

The same expression results if Eq. (2) is integrated by one form²³ of the Beattie-Bridgeman equation of state which expresses V as an explicit function of p and T , and if then terms containing powers of p higher than the first are dropped. Except for the terms involving the constant c , which does not occur in the Keyes equation of state, the above Eq. (9) is also equivalent to an approximate equation given by Keyes.¹⁶

For the quantity K_p^* which occurs in (9) we may use Eq. (5) which expresses K_p^* in terms of the energy and entropy constants and the heat capacities of the reacting gases. Or we may follow more closely the familiar treatment for ideal gases. One has every reason to expect that at very low pressure the van't Hoff isochor will hold. This we will write:

$$d \ln K_p^*/dT = \Delta H^*/RT^2. \quad (10)$$

Here ΔH^* is the heat absorbed in the reaction at zero pressure, and the derivative may be regarded as a total derivative. Kirchoff's law for the temperature coefficient of the heat of reaction is

$$d\Delta H^*/dT = \Delta C_p^* = \sum (\nu_i C_{p_i}^*). \quad (11)$$

In general C_p^* , the limiting value at zero pressure of the constant pressure specific heat, may be sufficiently well expressed as a function of the temperature by a series expansion:

$$C_{p_i}^* = R + A_i + B_i T + C_i T^2 \quad (12)$$

where R is the ideal gas constant and A_i , B_i , and C_i are constants for each gas.

Substituting (12) into (11) and integrating we obtain:

$$\Delta H^* = [\sum (\nu_i A_i) + \sum (\nu_i) R] T + \frac{1}{2} \sum (\nu_i B_i) T^2 + \frac{1}{3} \sum (\nu_i C_i) T^3 + I'. \quad (13)$$

Substitution of (13) into Eq. (10) and another integration give:

$$\ln K_p^* = \frac{\sum (\nu_i A_i) + \sum (\nu_i) R}{R} \ln T + \frac{\sum (\nu_i B_i)}{2R} T + \frac{\sum (\nu_i C_i)}{6R} T^2 - \frac{I'}{RT} + J' \quad (14)$$

Eq. (14) can be rearranged into the form

$$\log_{10} K_p^* - \frac{\sum (\nu_i A_i) + \sum (\nu_i) R}{R} \log_{10} T - \frac{M \sum (\nu_i B_i)}{2R} T - \frac{M \sum (\nu_i C_i)}{6R} T^2 = \frac{I}{T} + J \quad (15)$$

where M is the modulus of the common logarithms, 0.43429, \dots $I = -MI'/R$ and $J = MJ'$.

When an expansion similar to (12) (but omitting the constant R) is substituted into Eq. (5) for C_{V_i} , a relation similar to (15) results in which I

²³ Beattie, Proc. Nat. Acad. Sci. 16, 14 (1930).

and J are related to the energy and entropy constants of the reacting gases. These relations will be considered in a later paper.

III. TREATMENT OF THE DATA

Eqs. (9) and (15) are the basis for the present calculations. The former relation contains only the equation of state constants of the reacting gases, while the latter contains the heat capacity constants for the reacting gases and two arbitrary constants. Thus for the calculations of the effect of both pressure and temperature on the Haber equilibrium there are used only two adjustable constants, I and J , one of which might have been determined from a heat of reaction.

The data treated are those of Haber²⁴ which are at 30 atmospheres and extend from 561 to 952°C; and those of Larson and Dodge⁷ and of Larson⁸ (working at the Fixed Nitrogen Laboratory) which extend from 10 to 1000 atmospheres and from 325 to 500°C.

The equation of state constants for the various gases have been determined²⁵ from the available compressibility data, and are given in Table I.

TABLE I. *Values of the equation of state constants for the reacting gases. Units: normal atmospheres, liters per mole, degrees Kelvin ($T^{\circ}\text{K} = t^{\circ}\text{C} + 273.13$), $R = 0.08206$.*

Gas	A_0	B_0	c
Hydrogen	0.1975	0.02096	0.0504×10^4
Nitrogen	1.3445	0.05046	4.20×10^4
Argon	1.2907	0.03931	5.99×10^4
Ammonia	2.3930	0.03415	476.87×10^4

It will be noted that the constants for argon have been included. The reactant gas mixtures of hydrogen and nitrogen used by Haber, Larson and Dodge, and Larson contained 0.3 volume percent (which we shall assume to mean 0.3 mole percent) of argon. This argon must be taken into account in the calculation of the mole fractions of the gases composing the equilibrium mixtures from the stated analytical results, and must be included in the summation $\Sigma(x_i A_{0i}^{1/2})$ of Eq. (9); but does not enter elsewhere.

Larson and Dodge, and Larson calculated values of K_p from their analytical results by use of an approximate formula²⁶ that introduced errors which are now seen to be greater than those of experiment. Accordingly the values of K_p for these data were recalculated by use of the exact expression

$$K_p = \frac{\alpha/(1 + \alpha)^2}{[q - 3\alpha/2(1 + \alpha)]^{3/2} [r - \alpha/2(1 + \alpha)]^{1/2} p} \quad (16)$$

where α is the mole fraction of ammonia in the equilibrium mixture, q and r are the mole fractions of hydrogen and nitrogen in the reactant gas mixture,

²⁴ Haber, *Zeits. f. Elektrochemie* 21, 89 (1915).

²⁵ See reference (22) for the constants for H_2 , N_2 , and A. The values of the constants for NH_3 are given by Beattie and Lawrence, *J. Am. Chem. Soc.* 52, 6 (1930).

²⁶ Gillespie, *Jour. Math. and Phys.* 4, 84 (1925), especially p. 95.

being 0.762 and 0.235 respectively for these data. The values of K_p given by Haber were also checked by use of (16) and the given analytical data, the values of q and r being 0.752 and 0.245 for these data.

From the mole fraction of the gases in the equilibrium mixtures and the equation of state constants given in Table I, a value of K_p^* was calculated by use of Eq. (9) corresponding to each "measured" value of K_p (computed from Eq. (16)). At each temperature the values of K_p^* resulting from the treatment of the data at that temperature should be the same within the experimental error if Eq. (9) represents the pressure variation of K_p .

In order to correlate the values of K_p^* at different temperatures with the aid of Eq. (15) the specific heat constants A_i , B_i , and C_i were derived from the empirical equations of other observers, the reduction from 1 atmosphere to zero pressure being made by use of the relation

$$c_p = c_p^* + \left[\frac{2A_0}{RT^2} + \frac{12C}{T^4} \right] p \quad (17)$$

which gives sufficiently well the effect of pressure on specific heat.²⁷ These constants are given in Table II.

TABLE II. Values of the heat capacity constants of Eq. (12). Units: 15° calories per mole and per degree C; $R=1.986847$.

Gas	A	10°B	10°C	Ref.
Hydrogen	4.66	0.70	0.00	28
Nitrogen	4.82	0.33	0.05	29
Ammonia	6.04	0.71	5.10	30

The values of the left hand member of Eq. (15) were computed using the values of K_p^* obtained as described above and this quantity plotted against $1/T$. The values of the two adjustable constants I and J were determined from the best straight line drawn through the points, the deviations of the observed points from this line being shown in Fig. 1.

Knowing the two constants I and J we can compute K_p for any pressure and temperature by use of Eqs. (9) and (15). When the numerical values of all of the constants are included these equations become:

³⁰ Haber and Tamaru, Zeits. f. Elektrochemie **21**, 228 (1915). The values of C_p calculated by extrapolating the equation of Haber and Tamaru do not agree very well with the measurements of Osborne, Stimson, Sligh and Cragoe, Scientific Papers of Bureau of Standards **20**, 65 (1925). However the integral of $C_p^* dT$ from 0° to 150°C is in rather good agreement with the integrated value obtained from the results of the latter investigators, the difference being 3.7 calories per mole. The constants given are sufficiently accurate for our purposes.

$$\log_{10} K_p/K_p^* = \left[\frac{0.1191849}{T} + \frac{25122730}{T^4} + \frac{38.76816}{T^2} \Sigma(x_i A_{0i}^{1/2}) + \frac{64.49429}{T^2} (\Sigma x_i A_{0i}^{1/2})^2 \right] p \quad (18)$$

$$\log_{10} K_p^* = -2.691122 \log_{10} T - 5.519265 \times 10^{-5} T + 1.848863 \times 10^{-7} T^2 + \frac{2001.6}{T} + 2.6899 \quad (19)$$

where p is in atmospheres and T in degrees Kelvin; while x_i is the mole fraction of gas i in the equilibrium mixture and for A_{0i} is used the numerical value of A_0 for gas i given in Table I. In the summation $\Sigma(x_i A_{0i}^{1/2})$ the argon

Fig. 1. Deviation of the observed value of $\log_{10} K_p + f(T)$, the left hand member of Eq. (15) from the best straight line through the points.

must be included. In evaluating this summation the experimental values were used for the x_i 's. This introduces a slight inconsistency since the values of x_i used in Eq. (18) should be those resulting from the solution of this equation. However the differences between the experimental and calculated values of x_i were sufficiently small so that the use of the latter values would in no case change the last figure given for α by more than one unit and this only at the highest pressures.

In Table III are given the values of the percentages of ammonia in the equilibrium mixture α computed from the "calculated" values of K_p resulting from Eqs. (18) and (19). There are also given the observed percentages, and in the last column the percentage deviation (percentage based on the observed mole percent of ammonia found in the equilibrium mixture). For the calculation of α from K_p , which is tedious to make directly, an approximate correction formula was derived by logarithmic differentiation of Eq. (16), which gives:

$$\Delta \alpha = \frac{2.3026 \Delta \log_{10} K_p}{\frac{1}{\alpha} - \frac{2}{1+\alpha} + \left[\frac{1}{1+\alpha} \right]^2 \left[\frac{2.25}{q - 3\alpha/2(1+\alpha)} + \frac{0.25}{r - \alpha/2(1+\alpha)} \right]} \quad (20)$$

TABLE III. Comparison of observed and calculated values of the mole percentages of ammonia in the equilibrium mixture.

The "calculated" values of the mole percentage of ammonia α give when substituted in Eq. (16) the values of K_p computed from Eqs. (18) and (19), and may be regarded as the best available values of α .

by means of which the change in the mole fraction of ammonia in the equilibrium mixture $\Delta\alpha$ can be computed for a given change in $\log K_p$. Thus from each observed value of α and K_p , a value of α corresponding to the "calculated" K_p was obtained. This procedure was checked in several cases by calculation of K_p by substitution of the corrected values of α into Eq. (16).

In Fig. 2 is given a plot of the percentage deviation between the observed and calculated mole percentages of ammonia in the equilibrium mixture.

Fig. 2. Percentage deviation in the percentage α of ammonia in the equilibrium mixture. Each ordinate division represents 1%. A heavy base line representing zero deviation is used for each isobar.

IV. DISCUSSION OF THE RESULTS

The results of the calculations reported in Table III and exhibited in Figs. 1 and 2 may be briefly summarized as follows.

The average deviation in K_p for the results of the Fixed Nitrogen Laboratory is 1.18% and for those of Haber 1.09%, the average for all measurements being 1.16%. The distribution of positive and negative deviations is fairly good and it should be noted that with the exception of one point, the greatest errors do not occur at the extremes of pressure or temperature. This indicates that the equation is not failing progressively as the pressure or temperature is increased.

There is no indication of a discontinuity between the low pressure data of Larson and Dodge and the high pressure data of Larson. The discontinuity previously observed²⁶ in empirical smoothing was evidently produced by the use of inappropriate variables for the correlation. This is a case in which rational aid was clearly required for the discovery of appropriate variables.

The average difference between the observed and calculated mole percentages of ammonia in the equilibrium mixture, in percent of the observed mole percentage, is 0.73% for the Fixed Nitrogen Laboratory data, 1.08% for the Haber data, and 0.80% for both sets. We believe that this is well within the experimental accuracy of the measurements.

The calculated values of K_p and likewise of the percentage of ammonia α in the equilibrium mixture may be regarded as the best value deducible from the existing experimental observations. Our equation indicates that K_p and α depend on other variables than the temperature and pressure, for instance on the composition of the reactant gas mixture used in the production of ammonia (or on the equilibrium composition). Consequently Eq. (18) contains more information than can be presented in the form of a table such as Table III. This will be treated in a later paper.

V. CALCULATION OF THE COMPOSITION OF THE EQUILIBRIUM MIXTURE FROM THE INITIAL COMPOSITION

The calculation of the composition of the equilibrium mixture from the initial composition of the reacting mixture cannot be very conveniently made from Eq. (9), since the x_i 's in this relation are the equilibrium concentrations. However the last term of (9) is small¹⁰ in comparison with the other terms and may be neglected for a first approximation, giving Eq. (7) which does not contain any compositions. Thus in order to compute the composition of the equilibrium mixture at any pressure and temperature when the equation of state constants and the heat capacities of the reacting gases are given and the two constants I and J are known, we proceed as follows:

- (1) Compute a provisional value of K_p by use of Eqs. (7) and (15).
- (2) Calculate the corresponding provisional composition of the equilibrium mixture from the equation connecting K_p and these compositions. For the ammonia synthesis equilibrium this relation is Eq. (16).
- (3) Using these provisional equilibrium concentrations calculate a more exact value of K_p by use of Eq. (9), and correct the provisional equilibrium concentrations by use of an approximate correction formula similar to Eq. (20). In general even at the highest pressures no further approximation will be necessary. If required, however, these corrected equilibrium concentrations can be substituted again into Eq. (9) and a final value for K_p computed.

For the Haber equilibrium Eq. (7) becomes

$$\log_{10} K_p/K_p^* = \left[\frac{0.1191849}{T} + \frac{91.87212}{T^2} + \frac{25122730}{T^4} \right] p. \quad (21)$$

At 475°C and 1000 atmospheres Eq. (21) gives 0.01250 for K_p and the corresponding provisional value for α is 60.5%. From (18) and the provisional composition we find a value of 0.01483 for K_p , or 62.9% for α . One further approximation gives for the mol percent of ammonia at equilibrium, 63.2%, which is identical with the value given in Table III. For this calculation we have used $q = 0.762$ and $r = 0.235$ in Eqs. (18) and (20).

THE DIELECTRIC CONSTANT OF CARBON DIOXIDE AS
A FUNCTION OF TEMPERATURE AND DENSITY¹

BY FREDERICK G. KEYES AND JOHN G. KIRKWOOD**

RESEARCH LABORATORY OF PHYSICAL CHEMISTRY, MASSACHUSETTS INSTITUTE
OF TECHNOLOGY*

(Received June 12, 1930)

ABSTRACT

The dielectric constant of carbon dioxide has been measured over a wide range of temperature and density. It has been found that the Clausius-Mosotti function $(\epsilon-1)V/(\epsilon+2)$, although independent of temperature increases slowly with increasing density.

THE polarization of molecules by an homogeneous electric field has received adequate theoretical treatment. Both classical mechanics² and quantum mechanics³ lead to the following expression for the mean electric moment, m , of a molecule in weak fields at moderately high temperatures:

$$m = \left(\alpha + \frac{\mu^2}{3kT} \right) F$$

where F is the field strength, α the sum of the electronic and atomic polarizabilities, μ the permanent electric moment of the molecule, k Boltzmann's constant, and T the absolute temperature. The applicability of the above expression is further limited by the requirements that the frequency of the applied field be lower than any of the characteristic frequencies of the molecule, and that no transitions in internal atomic and electronic energy states occur with changing temperature.

The theory has been used with a large measure of success in the study of the molecular structure of gases of low density and of substances in dilute solution. In these cases the internal polarizing field may be calculated with very little ambiguity, and it is possible to obtain a relation between the dielectric constant of the substance and the constants α and μ of its constituent molecules.

The application of the theory to gases at high densities as well as to liquids and solids, has, however, been attended by great uncertainty because of the difficulty in calculating the average internal field effective in polar-

izing a molecule. The only guide in this matter has been the Clausius-Mosotti relation, which gives the molecular polarization as

$$\frac{\epsilon - 1}{\epsilon + 2}V = \frac{4\pi N}{3} \left(\alpha + \frac{\mu^2}{3kT} \right)$$

where N is the Loschmidt number, ϵ the dielectric constant, and V the molal volume. Several attempts have been made to verify the Clausius Mosotti law experimentally. Measurements of Tangl⁴ indicate that is valid up to a hundred atmospheres for air, nitrogen, and hydrogen at 20°C. It is to be noted, however, that the largest of his values of $\epsilon - 1$ are still so small that it is evident that the contribution of the polarization of the dielectric to the internal field is very small relative to the contribution of the external applied field. Measurements of Phillips⁵ on the refractive index of

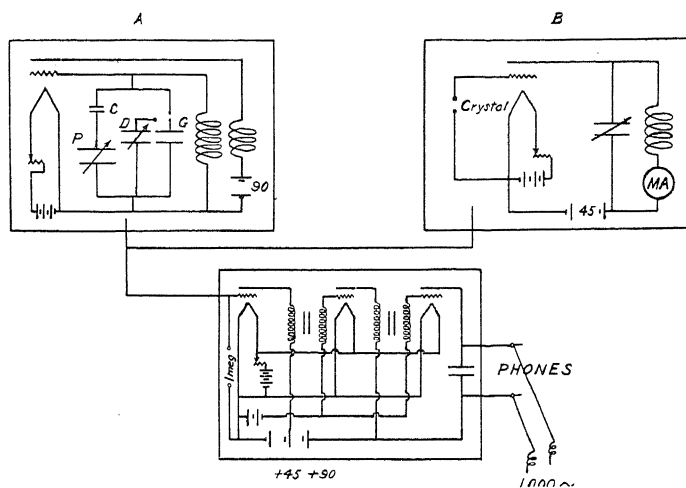

Fig. 1. Diagram of oscillator circuits.

carbon dioxide indicate that the corresponding Lorentz-Lorenz relation is valid even as far as the critical density for this substance. But the great experimental difficulties involved in the measurement of the refractive indices of compressed gases would make a verification of the values desirable.

In the present paper measurements of the dielectric constant of carbon dioxide over a wide range of temperature and density will be presented. We believe that they throw an important light on the limitations of the Clausius-Mosotti law, which the customary deduction, depending upon the cavity method for calculating the internal field, does more than suggest.

METHODS AND APPARATUS

Measurements of the dielectric constant were carried out by a resonance method which depended upon counting the beats between two heterodyne

⁴ K. Tangl, *Ann. d. Physik* **29**, 59 (1908).

⁵ P. Phillips, *Proc. Roy. Soc. A* **47**, 225 (1920).

oscillators. Since this method has been widely used in recent years, a detailed description will not be undertaken. The oscillator circuits (Fig. 1) were similar to those of Zahn.⁶ Oscillator *A* contained a condenser circuit consisting of the precision condenser *P*, the fixed mica condenser *C*, the gas condenser *G*, and the counterpoise condenser *D*. The precision condenser was a General Radio Variable Air Condenser, type 220, calibrated at the

Fig. 2. Diagram of gas condenser.

Bureau of Standards. Sangamo fixed mica condensers of capacity appropriate to the magnitude of the dielectric constant to be measured occupied the position of *C*. All auxiliary capacities were calibrated in terms of the precision condenser at the working frequency. Oscillator *B* was maintained at a constant frequency of 1010 k.c. by means of a General Radio quartz crystal. The heterodyne note was amplified and then compared with the

⁶ C. T. Zahn, Phys. Rev. 23, 781 (1924).

1000 cycle note of a mechanical oscillator. The resulting beats were counted in telephone receivers.

The gas condenser, Fig. 2, was constructed of chrome vanadium steel. The high potential side consisted of a solid cylinder held in position by two quartz supports, conically ground at both ends and fitting accurately into the end members of the cell. The low potential side of the condenser consisted of a shell, one millimeter in thickness. The separation of the cylinder and shell was 0.3 mm. The length of the condenser was 16 cm. The entire cell was surrounded by a steel jacket which bore the stress of the pressure, reducing the elastic deformation of the condenser itself to a minimum. The correction for deformation due to compression of the walls never amounted to more than one percent of $\epsilon - 1$. The outer jacket was closed at the lower end and made pressure tight by means of an aluminum washer. The insulating joint, inset Fig. 2, which carried a lead from the oscillator to the inner cylinder of the condenser was constructed in the following manner. A two centimeter length of two millimeter steel tubing was welded into a seven centimeter length of three millimeter steel tubing. This was silver soldered into a fitting which was later made tight in the head of the gas cell by means of an aluminum washer. A section of lead glass capillary coated with a flux of the same coefficient of expansion as the steel was fused to the inner tube and around the platinum wire leading from the inner cylinder of the condenser. Below the seal, the lead was protected by a length of quartz capillary extending down to the point where it was made fast in the cylinder.

The free capacity of the gas cell was found to be $167.4\mu\mu f$. It was roughly calculated to be $165\mu\mu f$ from the dimensions of the cell.

The temperature of the gas cell was controlled in an oil bath of large heat capacity by means of a mercury regulator. Temperatures were measured with a platinum resistance thermometer.

The pressure line was constructed of Shelby steel tubing with double cone connections. Connection with the pressure gauge, of the floating piston type,⁷ was made through a mercury-in-steel U.

At the beginning of a series of measurements the oil bath was brought to the desired temperature and the variable condenser D was adjusted to the same capacity as the evacuated gas cell. They could be alternately inserted into the oscillator circuit by a switch of small capacity. Gas was then admitted from a steel reservoir in the pressure line, and the pressure brought approximately to the desired value by heating or cooling the reservoir. It was finally adjusted to the proper value by means of a mercury piston compressor. From the two readings of the precision condenser with G and D alternately in the circuit, the dielectric constant could be calculated. After completing a measurement, the pressure was increased by means of the mercury piston and measurements made at regular pressure intervals. The use of the counterpoise condenser D made it possible to compensate

⁷ F. G. Keyes and Brownlee, *Thermodynamic Properties of Ammonia*, Wiley and Sons 1916. F. G. Keyes and J. Dewey, *J.O.S.A.* 14, 491 (1927).

for drift in the oscillator between measurements. The dielectric constant was calculated by the following formula, evident from the condenser circuit:

$$\epsilon - 1 = \frac{C^2(P_2 - P_1)}{(P_1 + C)(P_2 + C)G_0}$$

Here P_1 and P_2 are the two readings of the precision condenser, C the capacity of the fixed condenser, and G_0 the free capacity of the gas condenser.

For each series of measurements, the function $(\epsilon - 1)/(\epsilon + 2)$ was plotted against the density. The point at which the extrapolated line intercepted the axis of $(\epsilon - 1)/(\epsilon + 2)$ was taken as the zero point to which all of the values of $\epsilon - 1$ were referred. The intercept was in every series of measurements small and sometimes negligible. It was evidently the result of an initial extraneous capacity change attending the introduction of the gas, caused by incomplete temperature equilibrium in the evacuated gas cell.

EXPERIMENTAL RESULTS

Measurements of the dielectric constant of carbon dioxide were made upon the gas at 35°, 70°, 100°; and upon the liquid at 0°. The results are listed in the following tables.

TABLE I. *Measurements on gaseous carbon dioxide at 100°.*

The molal volumes were obtained from Amagat's pressure volume temperature measurements, the best at present available for carbon dioxide. The Clausius-Mosotti function, $(\epsilon - 1)/(\epsilon + 2) V$, is expressed in cubic centimeters

Fig. 3. The points above the density 20 are for the liquid at 0°; the others are for the gas at 100°.

per mol. At 35° above 60 atmospheres, the Clausius-Mosotti function, when plotted against the density, shows very great irregularity. We believe this to be due to error in Amagat's data, extremely probable in view of the very large value of $-(dV/dP)$ in this region. Except in this region, the

maximum error in measurements of Amagat which have been used is probably about 0.25%.

Extrapolation of $(\epsilon-1)V/(\epsilon+2)$ calculated from our measurements yields a value of about 7.4 cc in the low density region covered by other investigators. This is in satisfactory agreement with the value 7.3 cc calculated from the measurements of Zahn.⁸ We estimate the maximum random experimental error in $\epsilon-1$ to be $\pm 0.5\%$. With increasing density, it becomes progressively smaller. Absolute error originating in the calibration of the apparatus, we believe to be not more than one percent.

DISCUSSION

Within the limit of our experimental error, the Clausius-Mosotti function $(\epsilon-1)V/(\epsilon+2)$ is found to be independent of temperature. It is not, however, independent of density. To illustrate its behavior, $(\epsilon-1)V/(\epsilon+2)$, for the gas at 100°, as well as for the liquid at 0°, has been plotted against density in Fig. 3. The curve rises slowly with increasing density, but there is a gradual decrease in slope so that when the liquid densities are reached, it has become, within the limit of observation, parallel to the density axis. It is to be remembered however, that the deviation from the line

$$\frac{\epsilon-1}{\epsilon+2}V = \text{constant}$$

required by the Clausius-Mosotti law in its usual form, is small. Indeed the total increment in $(\epsilon-1)V/(\epsilon+2)$ in passing from the gas at the lowest density of the measurement to the liquid is only four percent.

A few brief speculations relative to the cause of the observed deviation from the Clausius-Mosotti law may be of value. The calculation of the average internal polarizing field F by the familiar cavity method yields

$$F = E + \frac{4\pi}{3}P \quad (1)$$

where E is the mean electric intensity in the dielectric and P the polarization per unit volume. The following formal generalization of the above expression has been suggested:

$$F = E + \nu P. \quad (1a)$$

Let us write

$$\nu = \frac{4\pi}{3} + \beta.$$

We also have at our disposal the familiar relations involving the displacement, D .

$$D = \epsilon E \quad (2)$$

$$D = E + 4\pi P \quad (3)$$

⁸ C. T. Zahn, Phys. Rev. 27, 455 (1926).

Moreover

$$P = \frac{N}{V} p_0 F$$

where N is the Loschmidt number, V the molal volume, and p_0 the molecular polarizability, $\alpha + \mu^2/3kT$. Elimination of D , E , and F from (1a), (2) and (3) gives

$$\frac{\epsilon - 1}{\epsilon + 2} V = \frac{4\pi N}{3} p_0 \frac{1}{1 - \beta N p_0 \rho} \quad (4)$$

where ρ is the density in mols per cubic centimeter. Eq. (4) may be made to conform to the curve of Fig. 3, if the polarizability p_0 is assumed to be a function of density of appropriate form. Change in the polarizability of a molecule with density could be attributed only to a change in the internal structure of the molecule or to molecular association. Such an hypothesis does not seem desirable without independent confirmatory evidence and in any case is of a purely qualitative nature. The fact that the carbon dioxide molecule gives no evidence of possessing a permanent electric moment is unfavorable to this type of explanation. Indeed, the polarizability, α , associated with the perturbation of the electronic orbits is not greatly affected even by interaction involving actual valence forces.

We are inclined to believe the cavity method of calculating the internal field is inexact and that the formal generalization (1a) is valid only if β is a function of density. If this view is accepted, we must conclude that the Clausius-Mosotti function, while furnishing a good approximation, is not an exact representation of the molecular polarization, $4\pi N p_0/3$, except in the limiting case of infinitely low density.

In conclusion, we wish to express our cordial appreciation to Professor H. B. Phillips for continued advice regarding the electrical circuits employed in these measurements.

SOME APPLICATIONS OF THE THEORY OF PLASTIC DEFORMATIONS OF DUCTILE METALS

BY A. NADAI

RESEARCH LABORATORIES, WESTINGHOUSE E. AND M. CO.*

(Received July 7, 1930)

ABSTRACT

A brief account will be given of the principal conditions which are available to express the equilibrium of stress in the plastic state of ductile metals. These conditions will be discussed for the case of rotationary symmetry in a plastic body. As an example several cases of plastic flow in a thick walled cylinder subjected to high internal pressure with and without longitudinal expansion will be treated. The distribution of stress during yielding is given for a long cylinder and for a flat ring, both subjected to radial pressure. How yielding and the plastic deformation spread through the walls of the cylinder has been shown.

1. GENERAL CONSIDERATIONS

CERTAIN ductile metals such as mild steel, if subjected to a state of homogeneous stress with increasing principal stresses show the remarkable behaviour of having a sharply defined limit of plasticity. It has been shown by numerous tests made within the last few years that for practical purposes, the reaching of the plastic state in a ductile polycrystalline metal such as steel, which has a well-defined limit of plasticity, under ordinary temperatures, depends on a stress-condition. This means that the plastic state is reached if a certain condition containing only the principal components of the stress tensor is fulfilled. Under a sharp limit of plasticity or a well-defined yield point it is understood, that permanent parts of the strain begin to develop only if the stresses satisfy the condition of plasticity mentioned before, and if the quantity expressed by the principal stresses on the left side of this condition is smaller than its limiting value a polycrystalline metal behaves like a perfectly elastic and isotropic material.

In this statement, the fact is included that in the first approximation it shall be permitted to assume that within certain amounts of plastic strain (of some few percent of the principal unit elongations) after the plastic limit has been reached, the three principal stresses do not change appreciably. In other words, it is permitted to assume that when plasticity is reached, the stresses remain constant and are independent of deformation as well as of the velocity of deformation.

A further consequence of these assumptions is that in general in a stressed body there will exist an elastic and a plastic region (or more plastic regions separated by elastic regions). In the plastic regions the deformations will have an elastic as well as a permanent part, while in the elastic region no permanent deformations exist.

* Scientific Paper No. 434.

By these restricting assumptions, the treatment of the problems of plastic flow is reduced from a question of dynamics to a question of pure statics. Hence, the six components of the stress tensor will have to be computed from the quasistatic equilibrium conditions, which will be identical with the equilibrium conditions of the stresses in an elastic material. They will also have to satisfy the conditions of plasticity and certain conditions expressing the manner in which stress and strain are connected during a steady, slow plastic flow.

It should be mentioned, that it is not difficult to work out the analysis of plastic flow under more general assumptions and to find solutions in certain simpler cases of plastic flow. It is thought to include in the assumptions such an experimentally known phenomenon as work hardening,¹ i.e. the fact that the stresses under which a metal is deformed plastically are dependent on the deformation and that the yield stresses gradually increase from zero with deformation. It is known that in soft annealed metals such as soft polycrystalline aluminum or copper, the plastic parts of the deformation are already developing under small stresses. In such metals a "yield point" cannot be observed if the annealed metal is stressed from the unstressed state. (But a yield point may appear and can be observed, if the metal was stretched to a certain amount, unloaded, and *again* stressed in the same sense). In this case, it is also not possible to distinguish a "plastic" portion within the stressed body from an "elastic" region, because the permanent part of the resulting strains increase gradually from zero and are hence encountered in all elements of the stressed piece of metal.

In this paper such cases will not be included, because the stress curves obtained by the simpler assumptions show already the characteristic facts related to the special cases of plastic flow treated here.

Regarding another effect, namely, the effect of the velocity of plastic deformation on the magnitude of the yield stresses producing this, it should be mentioned that tests made with single metal crystals as well as with polycrystalline ductile metals have shown that this effect is more pronounced at elevated temperatures (phenomenon of creep). For the plastic flow of steel at room temperatures, the effect can be considered as of a secondary order, if such phenomena as impact are excluded.

2. THE PLANE PROBLEM

If the stresses and strains depend only on two coordinates, for example, x, y , if rectangular or r, ϕ , if polar coordinates are chosen, we may distinguish two special cases in a similar manner as in the theory of elastic plane problems. We designate with s_x, s_y, s_z , the three components of normal stresses, with s_{xy} the only component of shearing stress, which is not vanishing, with $\epsilon_x, \epsilon_y, \epsilon_z$ the three components of strain and with ϵ_{xy} the unit shear component which is not vanishing.

¹ Some cases including the effect of work hardening were worked out in detail in A.S.M.E. Transactions, 1930.

3. THE PLANE STRAIN

In this case the unit extension $\epsilon_z = \text{constant}$, is a principal strain. Many examples of engineering practice are comprised under this heading. One case is especially simple, namely if $\epsilon_z = 0$. In this case the normal stress s_z is

$$s_z = \frac{1}{2}(s_x + s_y). \quad (1)$$

This follows from a rule of plastic flow.² If s_1, s_2 , and s_3 are the principal stresses and $\epsilon_1, \epsilon_2, \epsilon_3$ the principal strains during a steady slow plastic flow in which the directions of principal stresses do not change relatively to the stressed material, then

$$\frac{2s_2 - s_1 - s_3}{s_1 - s_3} = \frac{2\epsilon_2 - \epsilon_1 - \epsilon_3}{\epsilon_1 - \epsilon_3}. \quad (2)$$

Taking, for example, $\epsilon_3 = \epsilon_2 = 0$ and assuming that the volume during plastic flow is not changed:

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = \epsilon_x + \epsilon_y + \epsilon_z = 0. \quad (3)$$

We see that

$$\epsilon_1 = -\epsilon_2 \text{ OR } \epsilon_x = -\epsilon_y$$

and with this (2) reduced to (1).

The following statements referring to plane strain with one vanishing principal strain $\epsilon_z = 0$ are limited to plastic regions where the permanent parts of the strains ϵ_x and ϵ_y are predominant, so that the elastic parts may be neglected. We may put then simply

$$s_z = \frac{1}{2}(s_x + s_y) \quad (4)$$

and we see that the principal stresses s_1 and s_2 are given by

$$\begin{aligned} s_1 &= \frac{s_x + s_y}{2} + s_m \\ s_2 &= \frac{s_x + s_y}{2} - s_m \end{aligned} \quad (5)$$

Where s_m designates the principal shearing stress

$$s_m^2 = \frac{(s_x + s_y)^2}{4} + s_{xy}^2. \quad (6)$$

In order to express the fact that we have an equilibrium of stresses in the plastic state, we have to introduce a *condition of plasticity*. Taking the general form of the second degree

$$(s_1 - s_2)^2 + (s_2 - s_3)^2 + (s_3 - s_1)^2 = 2s_0^2 = \text{const.}^3 \quad (7)$$

² See Der bildsame Zustand der Werkstoffe, J. Springer, Berlin, 1927 S. 51., or On the Mechanics of the Plastic State of Metals. A.S.M.E. Transactions, Applied Mechanics Division, 1930.

³ This condition of plasticity was proposed by R. v. Mises, by Huber, and H. Hencky and has been verified by the tests of W. Lode and Ros-Eichinger.

Where the constant s_0 designates the yield stress in pure tension, we see that this expression simplifies considerably and becomes

$$(s_1 - s_2)^2 = \frac{4s_0^2}{3} = \text{const.} \quad (8)$$

Writing the constant $s_0/3^{1/2} = k$ and using (5) and (6) this last equation can be expressed in terms of s_x , s_y , and s_{xy} as follows:

$$(s_x - s_y)^2 + 4s_{xy}^2 = 4k^2 = \text{const.} \quad (9)$$

This is the condition of plasticity for plane strain $\epsilon_z = 0$, which has to be combined now with the conditions of equilibrium.

$$\frac{\partial s_x}{\partial x} + \frac{\partial s_{xy}}{\partial y} = 0, \quad \frac{\partial s_y}{\partial y} + \frac{\partial s_{xy}}{\partial x} = 0. \quad (10)$$

A complete theory of integration of the three simultaneous equations for the three unknown functions s_x , s_y , and s_{xy} , has been worked out by H. Hencky⁴ and R. v. Mises.⁵ Solutions in polar coordinates including some properties of the so-called slip lines, which facilitate the discussion of the solutions have been investigated by the author.⁶

We may remark that the theory of plane plastic flow under the assumption $\epsilon_z = 0$ of a vanishing lateral extension ϵ_z is mathematically identical with the so-called theory of maximum constant shear. The only difference is, that the constant k in Eq. (9) has to be taken in the first theory $k = 2s_0/3^{1/2} = 0.577s_0$ and in the second $k = s_0/2 = 0.500s_0$.

If ϵ_z is not vanishing, but equals a constant, the theory is more complicated; one case is given below.

4. PLANE STRESS

In this case $s_z = 0$, the normal stress perpendicular to the xy plane vanishes. This case occurs in a thin sheet which is loaded in its plane, for example in a plate containing a circular hole and stretched in all directions by a uniform tensile stress. As in this case, the third principal stress $s_3 = 0$ vanishes, the condition of plasticity⁷ becomes in terms of principal stresses,

$$s_1^2 - s_1s_2 + s_2^2 = s_0^2 = \text{constant} \quad (11)$$

or in terms of the stress components s_x , s_y , and s_{xy} , in rectangular coordinates

$$s_x^2 - s_xs_y + s_y^2 + 3s_{xy}^2 = s_0^2 = \text{const.} \quad (12)$$

This equation again has to be combined with the two equilibrium conditions (10).

In rectangular coordinates s_1 and s_2 , equation (11) is that of an ellipse with the semi-axes $a = (2)^{1/2}s_0$ and $b = (2/3)^{1/2}s_0$. Hence in a thin plate stressed

⁶ A. Nadai, *Zeits. f. Physik*, 106 (1924).

⁷ The author is much indebted to Mr. H. Friedman, who has carried out the computation.

in its plane, no normal stress component can ever become larger than $2s_0/3^{1/2}$, which is the maximum value of either s_1 or s_2 as coordinates of a point of the ellipse. This is $=1.155s_0$. There is therefore a distinct difference between the two states of plane stress $\epsilon_z=0$ and $s_z=0$, if plastic flow is considered. In the case $\epsilon_z=0$, the normal stresses may exceed the yield stress s_0 for pure tension considerably, and there are singularities of the stresses possible (for example, a "center of compression"). In the second case $s_z=0$, no stress component can become infinite, and singularities are not possible in this sense.

5. LONG CYLINDER YIELDING PLASTICALLY UNDER INTERNAL PRESSURE.

Let s_r and s_t be the radial and tangential normal stress components and s_z the axial normal stress. If the cylinder is not expanding or contracting in axial direction, the unit extension $\epsilon_z=0$ and the stress components s_r and s_t are given by the two equations

$$s_t - s_r = \pm \frac{2s_0}{3} \quad (13)$$

$$\frac{d(rs_r)}{dr} - s_t = 0. \quad (14)$$

The first is the condition of plasticity, the second the condition of equilibrium. A set of solutions satisfying these two equations and the two bound-

Fig. 1. Plastic flow in thick hollow cylinder stress distribution when axial elongation ϵ_z is equal to zero.

dary conditions, that at the inner surface for $r=a$ the radial stress must become equal to the pressure p and at the outer surface for $r=b$, s_r must vanish:

$$\begin{aligned} &\text{for } r = a, s_r = -p \\ &\text{and for } r = b, s_r = 0 \end{aligned}$$

is given by

$$\left. \begin{aligned} s_r &= -\frac{2s_0}{3^{1/2}} \ln \frac{b}{r} \\ s_t &= \frac{2s_0}{3^{1/2}} \left(1 - \ln \frac{b}{r} \right) \\ s_z &= \frac{2s_0}{3^{1/2}} \left(\frac{1}{2} - \ln \frac{b}{r} \right) \end{aligned} \right\} \quad (15)$$

This distribution of stress is shown in Fig. 1. The pressure p under which the cylinder will yield from the inner to the outer surface is found by the first formula of (15) by taking $r=a$:

$$p = \frac{2s_0}{3^{1/2}} \ln \frac{b}{a} \quad (16)$$

There s_0 designates the yield stress in pure tension.

6. YIELDING OF THIN PLATE WITH CIRCULAR HOLE OR OF FLAT RINGS RADIALY STRESSED

In this case $s_z=0$ and we have to combine Eq. (12) or if expressed in terms of the radial and tangential stress components s_r and s_t :

$$s_t^2 - s_t s_r + s_r^2 = s_0^2 = \text{constant} \quad (17)$$

with the equilibrium condition

$$r \cdot \frac{ds_r}{dr} = s_t - s_r. \quad (18)$$

Using here instead of s_t and s_r two new stress variables

$$\begin{aligned} s &= (s_t + s_r): 2 \\ s' &= (s_t - s_r): 2. \end{aligned} \quad (19)$$

We see that (17) takes the simpler form:

$$s^2 + 3s'^2 = s_0^2. \quad (20)$$

To satisfy this equation we put

$$s = s_0 \sin \theta, s' = \frac{s_0}{3^{1/2}} \cos \theta \quad (21)$$

and (18) takes the form

$$\frac{rd}{dr}(s - s') = 2s' \quad (22)$$

or

$$\frac{rd}{dr} \left(\sin \left(\theta - \frac{\pi}{6} \right) \right) = \cos \theta \quad (23)$$

whence by integration:

$$r^2 = c^2 e^{3^{1/2} \cdot \theta} \cos \theta \quad (24)$$

where c is a constant of integration. To determine its value, we have to express the radial and tangential stresses with the help of θ

$$\left. \begin{aligned} s_r &= \frac{2s_0}{3^{1/2}} \sin \left(\theta - \frac{\pi}{6} \right) \\ s_t &= \frac{2s_0}{3^{1/2}} \sin \left(\theta + \frac{\pi}{6} \right) \end{aligned} \right\} \quad (25)$$

If for $r=b$ the radial stress s_r shall vanish, we see that θ must be taken

$$\text{for } r=b, \theta = \theta_b = \frac{\pi}{6}.$$

If $\theta < \pi/6$, s_r will become negative, the radial stress will be a compression. On the contrary, if $\theta > \pi/6$, $s_r > 0$ and will be a tensile stress. Evidently the former case corresponds to the case of a ring with internal pressure and the latter case to a ring or plate with external tension. Now taking $\theta_b = \pi/6$ for $r=b$, the constant c in (24) is determined:

$$b^2 = c^2 \cdot \frac{3^{1/2}}{2} \cdot e^{\pi(3)^{1/2}/6} \quad (26)$$

We get finally from (24) and (26) the relation between the radius r and the parameter θ

$$r^2 = \frac{2b^2}{3^{1/2}} \cdot e^{3^{1/2}(\theta - \pi/6)} \cdot \cos \theta. \quad (27)$$

Thus the complete solution is obtained.

To get the pressure or tension p which must act on the circumference $r=a$ and produce yielding, the angle $\theta = \theta_a$ must be computed from the last equation by taking $r=a$ and thus p is given by

$$p = \frac{2s_0}{3^{1/2}} \sin \left(\frac{\pi}{6} - \theta_a \right). \quad (28)$$

To each value of θ_a corresponds a value of the ratio b/a and a radial and tangential stress s_r and s_t for $r=a$. This has been shown in Fig. 2, where the ratio of the two radii b/a and the two stress components at the circle $r=a$ are represented by curves. To find the pressure p for a given ring, we have to read the value of s_r for $r=a$ (that is of p) below the value of b/a . The stress distribution is also shown in Fig. 3, where the radial and the tangential stresses s_r and s_t are plotted as functions of the radial distance r of a point of the ring from its center.

Comparing the type of curves in Fig. 3 with the logarithmic curves for the distribution of stress obtained for the case of the yielding of a long cylinder under internal pressure p , (Fig. 1.) it can be seen that in the latter case with the increasing thickness of the hollow cylinder the pressure p is indefinitely increasing. In the case of a flat ring with free faces and stressed radially by

a pressure p acting on the inner circle, however, equilibrium is only possible, if the ratio of the outer to the inner radius is

$$1 < b/a < 2.963$$

For $b/a > 2.963$, no plastic equilibrium is possible in which the ring yields from its inner to its outer cylindrical surface.

Fig. 2. Radial and tangential stress and ratio b/a plotted against parameter θ in circular plates with holes yielding under radial pressure.

7. PARTIAL YIELDING

Until now the only cases that have been treated were those in which the material in a hollow cylinder was yielding from the inner to the outer surface. If the pressure in a tube is gradually increasing from zero, the tube will be

Fig. 3. Distribution of stress in circular plates with central hole, yielding under radial pressure p . a inner, b outer, radius to yield strain in tension.

stressed at first only elastically. Later, with the increasing pressure an annular region will become plastic, growing from the inner surface. For such values of the pressure, the tube must be divided in two portions $a < r < c$, and $c < r < b$, of which the former is stressed beyond the limit of plasticity and the latter only elastically. If, for example, the tube cannot expand in

the axial direction ($\epsilon_z=0$), first yield will occur at a pressure given by the well known formula

$$p_0 = \left(1 - \frac{a^2}{b^2}\right) \frac{p_0}{3^{1/2}} \quad (29)$$

derived from the stress conditions of an elastic tube. If $p > p_0$, the elastic stress distribution in the region $r > c$, will be obtained from the stresses for an elastic cylinder

$$\left. \begin{aligned} s_r' &= c_1 + \frac{c_2}{r^2} \\ s_t' &= c_1 - \frac{c_2}{r^2} \\ s_z' &= 2\nu c_1 \end{aligned} \right\} \quad (30)$$

where ν is Poisson's ratio and c_1 and c_2 are two constants, and the plastic stress distribution in the region $r < c$ will be given by

$$\left. \begin{aligned} s_r &= c_3 + \frac{2s_0}{3^{1/2}} \ln r \\ s_t &= c_3 + \frac{2s_0}{3^{1/2}} (\ln r + 1) \\ s_z &= c_3 + \frac{2s_0}{3^{1/2}} \left(\ln r + \frac{1}{2} \right) \end{aligned} \right\} \quad (31)$$

The three constants c_1 , c_2 , and c_3 can be determined from the conditions of continuity and the boundary conditions of the cylindrical surfaces $r=a$ and $r=b$. The result of the computation is

$$\text{Stresses in the elastic portion } c < r < b \quad \left\{ \begin{aligned} s_r' &= \frac{s_0}{3^{1/2}} \gamma^2 \left(\frac{1}{u^2} - 1 \right) \\ s_t' &= \frac{s_0}{3^{1/2}} \gamma^2 \left(\frac{1}{u^2} + 1 \right) \\ s_z' &= \frac{2s_0\nu}{3^{1/2}} \gamma^2 \end{aligned} \right. \quad (32)$$

$$\text{Stresses in the plastic portion } a < r < c \quad \left\{ \begin{aligned} s_r &= -p + \frac{2s_0}{3^{1/2}} \ln \frac{u}{\alpha} \\ s_t &= -p + \frac{2s_0}{3^{1/2}} \left(\ln \frac{u}{\alpha} + 1 \right) \\ s_z &= -p + \frac{2s_0}{3^{1/2}} \left(\ln \frac{\mu}{\alpha} + \frac{1}{2} \right) \end{aligned} \right. \quad (33)$$

where

$$\frac{r}{b} = u, \quad \frac{a}{b} = \alpha \quad \text{and} \quad \frac{c}{b} = \gamma. \quad (34)$$

The pressure required to produce yielding in the tube to the radius $r=c$ is found by

$$p = \frac{s_0}{3^{1/2}} \left(2 \ln \frac{\gamma}{\alpha} + 1 - \gamma^2 \right) \quad (35)$$

where s_0 is the yield stress in pure tension.

In Fig. 4 the pressures p required to produce progressive yielding through a hollow cylinder are shown for different ratios of $\alpha=a/b=0.1, 0.2 \dots$.⁷ The abscissae in this figure are $\gamma=c/b$, the ordinates the pressure p . For example, the curve belonging to $\alpha=0.8$ shows how the pressure p in a tube

Fig. 4. Pressure p producing yielding plotted against ratio $\gamma=c/b$. c is radius of surface to which plastic region extends.

of the ratio a/b of the inner to the outer radius $=0.8$ would increase with the increasing radius c of the cylindrical surface, to which yielding has penetrated in the tube.

8. TUBE SUBJECTED TO INTERNAL PRESSURE AND AXIAL LOAD

The theory of the plastic flow of a thick walled cylinder which is exposed to a high internal pressure and which is permitted also to expand in the axial direction is considerably more complicated than the cases mentioned above with no axial expansion $\epsilon_z=0$. This case has been worked out elsewhere.⁸ We quote here the formulae. Let s and s' be

$$s = \frac{s_z + s_t}{2} - s_r, \quad s' = \frac{s_z - s_t}{2} \quad (36)$$

⁸ A.S.M.E. Trans., Applied Mechanics Division, 1930.

and u a variable parameter given by

$$u = \frac{1}{3^{1/2}} \left(1 + \frac{2\epsilon_a}{\epsilon_z} \right) \frac{a^2}{r^2} \quad (37)$$

where ϵ_a is the tangential unit elongation at the outer surface $r=a$ of the cylinder and ϵ_z the axial unit elongation, assumed to be uniform over the whole cross section of the tube, a is the outer radius, and b the inner radius of the tube.

Then the stress distribution is given by

axial stress:

$$s_z = s + s' + s_r \quad (38)$$

tangential stress:

$$s_t = s - s' + s_r \quad (39)$$

where

$$s = \frac{s_0}{2(3)^{1/2}} \cdot \frac{3^{1/2} + 3u}{(1 + u^2)^{1/2}} \quad s' = \frac{s_0}{2(3)^{1/2}} \cdot \frac{3^{1/2} - u}{(1 + u^2)^{1/2}} \quad (40)$$

and the radial stress is equal to

$$s_r = \frac{s_0}{3^{1/2}} \log_e \frac{u_a + (1 + u_a^2)^{1/2}}{u + (1 + u^2)^{1/2}} \quad (41)$$

The pressure p under which the whole tube will yield is

$$p = \frac{s_0}{3^{1/2}} \log_e \frac{u_b + (1 + u_b^2)^{1/2}}{u_a + (1 + u_a^2)^{1/2}} \quad (42)$$

with

$$u_a = \frac{1}{3^{1/2}} \left(1 + \frac{2\epsilon_a}{\epsilon_z} \right) \quad \text{and} \quad u_b = \frac{a^2}{b^2} u_a \quad (43)$$

A special case is that of a tube with no axial elongation $\epsilon_z=0$, where both constants u_a and u_b become infinite, but a careful consideration shows that the formulae (38–41) converge exactly to the simpler formulae already given by the Eqs. (15).

9. SUMMARY
